Runnability of Train on Transit Girder System.

For development of transit girder system, runnability of train had been studied as mentioned below.

Runnability of trains at the transit girder system can be separately checked for sections of the expansion joint and the dispersion system for angular bend.

At the expansion joint, the structure is designed so that rail tracks may continue to secure a proper gauge line and wheelset load can be structurally supported.

Rail of the inserted girder type expansion joint is cut out partially to keep space for expansion, and the guardrails are arranged to prevent derailment.

For the runnability on the expansion joint, running tests by actual cars were conducted in 1974 to certify safety of trains with speed up to 180 km/hr.

The runnability on the angular bend section is extremely influenced by a vertical and horizontal angular bend. The safety against derailment when a train run on the transit girder with vertical, horizontal angular bend or composite angular bend of the both and passenger's comfortableness for vertical and horizontal vibration had to be investigated.

The investigations for derailment and comfortableness were carried out for criteria of the rate of off-loading of wheels and the lateral pressure and magnitude of the vibration, respectively, and they were numerically analyzed or simulated for various types of cars.

And, important items among them were confirmed by running tests of actual cars and model cars, and results of the running tests and the calculation were compared. As the result of these investigations, relation between the running speed and the limit of angular bend is established as shown in right figure.

For example, when the total angular bend is 10‰ and span of the dispersion girder is 15m, these figures show that allowable velocity (V/V_{sr}) of Shinkansen is 1.07 for the rate of off-loading of wheels, in other words, Shinkansen car can run with 1.07 times speed of standard running speed. As for an electric locomotive, it can run with 1.04 times speed of 120 km/hr.

Allowable velocity V/V_{sr} above is defined as the ratio of investigated result to standard running speed

Allowable speed of various types of cars

INSTALLATION FOR RUNNABILITY ON LONG-SPAN BRIDGE

In Kojima-Sakaide Route of Honshu-Shikoku Bridge Project, suspension bridges and cable stayed bridges which have high flexibility are being constructed for highway and railroad with high speed trains.

At the end of these bridges, large amount of expansion/contraction and angular bend occur.

In order to let the high speed train run safely on these deformation, transit girder system has been developed.

Two types of expansion joint are developed.

One is called the inserted girder type for expansion (including effect of earthquake) up to ± 750 mm of suspension bridges.

And, another is called the moving sleeper type for expansion up to ± 400 mm of cable stayed bridges.

This research deals with the contribution of reinforced concrete slab of composite beams on the strength and the deformation capacity of steel beam-to-column connections subjected to seismic loading.

Dimension and configuration of specimens are shown in figure 1 and table 1. Relative yield strength of panel-zone to that of adjoining members is expressed marks "Rpy" and "sRpy" in table 1. Those are considered to be the key parameter on the evaluations of strength, deformation capacity and energy absorption of beam-to-column connections.

Figures 4a-4c are the summary of representative relations between load and shear deformation of panel-zone. Vertical axis represents the ratio of load to calculated yield strength of beam-to-column connection composed of bare steel beams and column, while horizontal axis represents the ratio of shear deformation of panel-zone to calculated yield shear deformation. Dotted lines in figures 4a-4c show the test results of beam-to-column connections of the same configuration without concrete slab. The reinforcing effect of steel beam-to-column connections by the reinforced concrete slabs of composite beam is illustrated.

A model to take the effect of concrete slab into consideration is proposed in figure 5. In this model, the strength of panel-zone is considered to increase by the enlargement of nominal volume of panel-zone as shown in the figure 5. Relation between "sRpy" (relative yield strength of panel-zone to that of adjoining steel members) and strength, deformation capacity and energy absorption are shown in figures 6a-6d with the other test results of beam-to-column connections composed of bare steel beams and column. The empirical formulas in figures 6a-6d are obtained by regression analyses on the test results of beam-to-column connections composed of bare steel beams and column. Shiftings to the estimated results of yield strength of enlarged panel-zone are indicated by arrows. The seismic behavior of steel beam-to-column connections with composite beams can be evaluated by making use of the model in figure 5 and empirical formulas in figures 6a-6d.

BEAM-TO-COLUMN CONNECTIONS WITH COMPOSITE BEAMS

Table 1 Specimens

No.	Specimen	Column	Beam	Slab type	R _{py}	sR _{py}
1	Z0-I	H-300x300x22x22	H-350x175x9x12	I	1.13	0.80

Optimum Design of Double-Layer Space Grids

Henning AGERSKOV

Assoc. Prof. of Struct. Eng.
Technical University of Denmark
Lyngby, Denmark

In recent years extensive and increasing use has been made of space trusses, especially in the form of double-layer space grids. These types of structures have in many cases been able to compete with more traditional constructions. The main areas of application have been sports halls, swimming pools, exhibition buildings, churches, shopping centres, hangars, factory buildings, etc., where the space grid is used as roof construction.

In the design, almost unlimited possibilities exist in practice for the choice of geometry of space trusses. This forms the background for a research project, in which the optimum design of double-layer space trusses has been investigated. As a first part of the investigation, a study covering what has, until recently, been obtained as regards optimization of double-layer space grids was carried out. With the results of this investigation as a starting point, various geometrical designs were studied in detail to determine the optimum design. Both square and rectangular grids have been investigated, under the assumption of either simple supports along the entire edge or column supports at the corners.

In determination of the optimum design, an ordinary mathematical optimization based on a minimum of material consumption, was found to be of little practical interest. The present investigation is based on assumptions concerning nodes, members, supports, loading, etc., which make the results realistic to a practical design. To determine the optimum de-

Fig. 1. Space grid systems, which will in general result in good overall economy.

sign, both the material consumption, the number of nodes, and the number of members in the structure have to be considered, while an optimum design based only on a minimum of material will rarely, if ever, be an economical optimum for a double-layer space grid.

On the basis of the results obtained in the investigation, guidelines for the structural engineer to obtain an optimum design, have been worked out. Guidelines are given for choice of overall geometry of simply supported and corner-supported square and rectangular space grids.

RECOMMENDATIONS

The following general recommendations concerning optimum design of double-layer space grids can be made:

1. The member density must be small. In addition to giving a small material consumption, this leads to a grid with relatively few nodal points and thus least possible production costs for nodes, erection expenses, etc.
2. The system should be chosen so that the space grid is built of relatively long tension members and relatively short compression members.
3. For rectangular, relatively long space grids, optimum design is obtained with systems where the load is mainly carried across the short span. Systems where the members in both top and bottom layer grids are parallel to the edges will generally result in the least material consumption.
4. If both the material consumption and the number of nodes and number of members are considered, the space grid systems shown in Fig. 1 a and b will, generally speaking, result in good overall economy. This could be concluded from investigations on both square and rectangular double-layer space grids, simply supported along the entire edge or column-supported at the corners.

STUB-GIRDER FLOOR SYSTEM

Full Scale Test Program at the University of Saskatchewan

Stub-Girder Floor System

401 West Georgia Project, Vancouver

Integration of Building Services into the Structural System

ADVANTAGES:
Integration of Building Services
Simplified Girder to Beam Connection
Reduced Building Heights, Lower Costs

APPLICATIONS IN CANADA:

Building	Storeys	Area (m ²)
Nova Building, Calgary	37	70,000
Manulife Bldg., Edmonton	24	71,000
401 West Georgia Project, Vancouver	22	28,000

ANALYSIS

Most Common Method of Analysis is to Model the Stub-Girder as a Vierendeel Girder and Then Use a Conventional Stiffness Program
