THE KROPHOLLER CONJECTURE

by Graham A. NIBLO and Michah SAGEEV

A finitely generated group G is said to *split over a subgroup* H if and only if G may be decomposed as an amalgamated free product $G = A *_H B$ (with $A \neq H \neq B$) or as an HNN extension $G = A *_H$. The Kropholler conjecture is concerned with the existence of such splittings.

Given a subgroup H of a finitely generated group G the *invariant* $e(G, H)$ is defined to be the number of *Freudenthal (topological) ends* of the quotient of the Cayley graph of G under the action of the subgroup H . This number does not depend on the (finite) generating set chosen for G (see [3]) so it is an invariant of the pair (G, H) .

For example, if G is a free abelian group and H is an infinite cyclic subgroup then $e(G, H) = 0$ if G has rank 1, $e(G, H) = 2$ if G has rank 2 and $e(G, H) = 1$ if G has rank greater than or equal to 3.

This invariant generalises Stallings' definition of the number of ends of the group G since if $H = \{1\}$ then $e(G, H) = e(G)$.

In [4] Stallings showed that the group G splits over some finite subgroup C if and only if $e(G) \geq 2$. There are several important generalisations of this fact, the most wide ranging being the algebraic torus theorem, established by Dunwoody and Swenson [1]. This states that, under suitable additional hypotheses, if G contains a polycyclic-by-finite subgroup H of Hirsch length n with $e(G, H) \geq 2$ then either

- (1) G is virtually polycyclic of Hirsch length $n + 1$,
- (2) G splits over a virtually polycyclic subgroup of Hirsch length n , or
- (3) G is an extension of a virtually polycyclic group of Hirsch length $n - 1$ by a Fuchsian group.

This theorem generalises the classical torus theorem from low-dimensional topology which asserts that a closed 3-manifold which admits an immersed incompressible torus either admits an embedded incompressible torus or has a Seifert fibration. These topological conclusions imply the algebraic conclusions for the fundamental group of the manifold.

An important ingredient of the proof of the algebraic torus theorem is a special case of the so-called Kropholler conjecture. Its original formulation relies on the following observation of Scott:

A subgroup H of a finitely generated group G satisfies $e(G, H) \geq 2$ if and only if G admits a subset A satisfying the following:

- (1) $A = HA$,
- (2) A is H -almost invariant, and
- (3) A is H -proper, i.e., neither A nor $G - A$ is H -finite.

We will refer to the subset A as a *proper H -almost invariant subset*.

In his proof of the algebraic torus theorem for Poincaré duality groups Kropholler observed that, under certain additional hypotheses, if G admits a proper H -almost invariant subset A such that $A = AH$, then G admits a splitting over some subgroup $C < G$ related to H (see [2] for an outline of the proof). He conjectured that the additional hypotheses were inessential. Specifically:

CONJECTURE 53.1 (The Kropholler conjecture). *Let G be a finitely generated group and $H < G$. If G contains a proper H -almost invariant subset A such that $A = AH$ then G admits a non-trivial splitting over a subgroup C which is commensurable with a subgroup of H .*

The conjecture is known to hold when G is a Poincaré duality group or when G is word hyperbolic and H is a quasi-convex subgroup. In general it is known (for an arbitrary finitely generated group G) whenever H is a subgroup which satisfies the following descending chain condition:

Every descending chain of subgroups $H = H_0 \geq H_1 \geq H_2 \geq \dots$ such that H_{i+1} has infinite index in H_i eventually terminates.

This condition holds for example for the class of finitely generated polycyclic groups, in which class the Hirsch length is the factor controlling the length of such a chain. This is a key ingredient in the proof of the full algebraic torus theorem.

An alternative, more geometric, point of view on the conjecture is provided by the following characterisation:

THEOREM 53.2. *Given a finitely generated group G and a subgroup $H < G$ the invariant $e(G, H)$ is greater than or equal to 2 if and only if G acts with no global fixed point on a $CAT(0)$ cubical complex with one orbit of hyperplanes, and so that H is a hyperplane stabiliser. H admits a right invariant, proper H -almost invariant subset if and only if the action can be chosen so that H has a fixed point in the complex.*
