An Occurrence of Bjarebyite in the Buranga Pegmatite, Rwanda

By *Oleg von Knorring* *) and *André-Mathieu Fransolet* **)

With 2 figures and 5 tables in the text

Abstract

A second occurrence of bjarebyite, $\text{Ba}(\text{Mn,Fe})_2(\text{Al,Fe})_2(\text{PO}_4)_3(\text{OH})_3$ is described from Buranga pegmatite in Rwanda. This rare pegmatitic phosphate is closely associated with bertossaite, trolleite, apatite and lazulite.

The monoclinic unit cell dimensions, calculated from the powder pattern data, are: $a = 9.103$, $b = 12.204$, $c = 4.959$ Å and $\beta = 100^\circ 28'$ with $Z = 2$. Specific gravity is 3.90. Complete chemical analyses are given. The optical properties are: $\alpha = 1.724$, $\beta = 1.727$, $\gamma = 1.749$ and $2V = (+) 38^\circ$. The pleochroism is strong.

An infrared spectrum is given and briefly discussed.

Introduction

Buranga is noted for its exceptional variety of phosphate minerals which have been described by THOREAU et al. (1950–1957), ALTMANN (1961) and GALLACHER and GERARDS (1963). During four brief visits to this pegmatite area between 1964–1969, specimens were collected mainly for a comparative study in connection with pegmatite investigations in south-west Uganda. As a result of laboratory examination many rare minerals including four new phosphates have been noted. (VON KNORRING and HORNUNG, 1965, VON KNORRING and MROSE, 1966 and VON KNORRING, 1965, 1969, 1970, 1972, 1973.)

The Buranga pegmatite is situated about 0.5 km north of the Minétain company's headquarters at Gatumba ($29^\circ 31' E.$, $1^\circ 55' S.$), some 50 km south of the administrative town of Ruhengeri in northern Rwanda. The rocks in this area belong to the Burundian system, comprising schists, quartzites, amphibolites and often dome-like granitic intrusives; they have a northerly

*) Department of Earth Sciences, The University of Leeds, U.K.

**) Institut de Minéralogie, Université de Liège, Belgium.

trend and are continuous with the Karagwe-Ankolean rocks on the Uganda side of the border to the north. Granite pegmatites are of common occurrence and many have been mined for cassiterite in the past.

The Buranga occurrence is dominated by a NNW-striking quartz core, some 10 metres wide, in the southern part of pegmatite. In relation to the main quartz core the pegmatite is asymmetrical and is less well developed on the eastern side where it is in contact with a tourmalinized amphibolite; westwards the pegmatite passes gradually into a pegmatitic granite. There is a marked zoning around the quartz core which contains conspicuous lath-shaped voids after giant spodumene crystals – a characteristic feature of many pegmatites in northern Rwanda and adjoining parts of south-west Uganda. Nodules and aggregates of phosphate minerals, some of gigantic proportions, are commonly observed within the quartz core or along the core margin. Next to the core there is a zone of albite and muscovite, partly kaolinized. Pockets of beryl and occasional aggregates of manganotantalite have been found in this zone, in addition to zircon, microlite and some uraniferous minerals.

A pistachio – to dark-green phosphate (now bjarebyite, MOORE et al. 1973) was observed at Buranga in 1965 and was subsequently identified by Miss MARY E. MROSE of the U.S. Geological Survey in Washington, who was then investigating an identical mineral found at the Palermo and Smith mines in New Hampshire.

Phosphate mineralization

The phosphate minerals in the Buranga pegmatite may be divided into three major associations as follows:

1. Manganese-iron nodules containing lithiophilite, heterosite-purpurite, ferrisicklerite, alluaudite, barian arrojadite, tavorite, barboselite, lipscombite, frondelite, strengite, metastrengite, stewartite, bermanite and a migidatite-like mineral.
2. Amblygonite (montebrasite) with minor lazulite (scorzalite), apatite, eosphorite and berlinitite.
3. Aggregates containing variable amounts of lazulite (scorzalite), trolleite, bertossaite, amblygonite, brazilianite, augelite, with some apatite, bjarebyite, crandallite, wavellite, wardite and three new fibrous phosphates under investigation.

Muscovite and quartz may be present in these associations.

Paragenesis

Bjarebyite belongs to the third major assemblage of the phosphate minerals from the Buranga pegmatite that VON KNORRING (1970) distinguished.

This very complex phosphates association is mainly characterized by abundance of aluminium.

VON KNORRING (1969, 1970 and 1972) noted many species in it: amblygonite, trolleite, brazilianite, lazulite, augelite, berlinitite, bertossaite with crandallite and wavellite. Quartz, apatite and muscovite also occur in the association.

Bjarebyite is pistachio-or dark-green in colour, striated and rather like tourmaline in appearance. It is found intimately intergrown with bertossaite, though it is usually confined to small cavities, lined with quartz and fibrous apatite, in trolleite or bertossaite.

Under the microscope, this Ba-bearing phosphate appears in hypidiomorphic forms, frequently associated with quartz and a blue phosphate of the lazulite-scorzalite series. Sometimes, it shows an interstitial structure with this blue phosphate, in trolleite.

Crystallography

Single-crystal X-ray data

Rotation and Weissenberg photographs were obtained from a short, striated, prismatic crystal of bjarebyite from Buranga pegmatite, using nickel filtered copper radiation.

The diffraction data show monoclinic symmetry, compatible with space group $P\ 2_1$ and $P\ 2_1/m$.

The recent determination by MOORE et al. (1973) confirms $P\ 2_1/m$ as the correct space group.

Preliminary cell parameters were obtained from measurements of these films. They were used to obtain the refined cell data from the powder diffractogram.

X-ray powder diffraction data

A diffractogram of bjarebyite was recorded on a Philips' diffractometer with an internal standard of oxammite (A.S.T.M. 14-801), using Ni-filtered copper radiation ($CuK_{\alpha} = 1.5418\ \text{\AA}$).

Powder data are listed in table I where patterns of bjarebyite from Palermo mine are also listed for comparison.

The unit cell dimensions were computed with the least-squares refinement FORTRAN program of COX (1967). The results are compared in table II with those recently reported by MOORE et al. (1973). The unit cell dimensions of bjarebyite from Buranga are greater and this seems to be related to the higher MnO amount in the formula (table IV).

G (calc)	3.924	4.02

Optical properties

Bjarebyite is biaxial positive. The refractive indices, measured in sodium light and determined with Cargille oils by the double variation method, are $\alpha = 1.724$, $\beta = 1.727$ and $\gamma = 1.749$ all values are accurate to ± 0.001 .

Birefringence, as observed with the Berek's compensator, is 0.022 and $(\gamma - \alpha) = 0.025$. The optic axial angle is (+) 38°, measured conoscopically on the universal stage. This value compares with (+40° 56'), calculated from refractive index data, and lies within the limits of error of the refractive indices as determined.

A strong pleochroism is observed:

Z, colourless to pale brownish yellow,
 Y, brownish green,
 X, apple or olive green.

Extinction angle between Z and *c* is 8° by universal-stage measurements and 7° as observed in thin section.

Y is assumed to be parallel to *b* and Z seems to lie in (010) in the acute angle β . Sections more or less normal to Z show strong dispersion ($r < v$) and two perfect cleavages, probably (010) and (100) (MOORE et al. 1973) (fig. 1).

These results are compared in table III with those obtained by MOORE et al. (1973). The difference between the optical data cannot be explained by chemical differences alone, in particular by the ratio Mn/Fe.

Fig. 1. Bjarebyite. Section nearly normal to Z showing two cleavages. Polarized crossed light.

1. Bjarebyite from Palermo mine. Oxides calculated from Moore' results (1973).
2. Analyst: O. VON KNORRING
3. VON KNORRING (1973) } Bjarebyite from Buranga pegmatite.
4. Mean of the two analyses (2 and 3).
5. Specific refractive energies (Larsen and Berman, 1934).

The mean of the two analyses (4), the measured specific gravity 3.90 and the unit cell volume 542 Å³ suggest a cell content Z=2 and a formula of

or an idealised formula of

The calculated specific gravity 3.924 is in good agreement with G. meas. = 3.90.

The mean index of refraction, calculated by the Gladstone and Dale rule (IV, 5) from the mean of the two analyses is 1.735, compared to the mean measured index of 1.733.

Infrared absorption spectrum

The IR spectrum was recorded with a Beckman IR-12 spectrophotometer in the 200 cm⁻¹-4000 cm⁻¹ region. The sample was prepared with 2 or 3 mg of bjarebyite diluted in pressed tablets of KI.

The infrared absorption spectrum of bjarebyite is given in figure 2. The wavenumber in cm⁻¹ and the characteristics of the peaks are given in table V.

Fig. 2. Infrared absorption spectrum of bjarebyite.

Table V. *Infrared absorption bands of bjarebyite*

Wavenumber (cm ⁻¹)	Wavenumber (cm ⁻¹)
225 s	582 w
275 m b	612 s
313 s b	655 m
355 s	871 s b
384 w	964 s
435 sh	1015 m b
452 s	1050 w b
472 w	1085 w b
491 m	1133 m b
513 w	1187 s
535 sh	3250 s b
545 s	3520 s
568 m	3540 s

s strong, m medium, w weak, b broad, sh shoulder

For the 200 cm⁻¹-700 cm⁻¹ region assignments of absorption peaks are very difficult and the complexity of the spectrum after 400 cm⁻¹ is probably due to the bending vibrations of isolated PO₄ tetrahedra, mixing with Al-O vibrations in the [Al₂O₆(OH)₃] chains, described by MOORE and ARAKI (1973) in the bjarebyite structure.

The numerous and strong frequencies from 900 cm⁻¹ to 1200 cm⁻¹ are these of the stretching vibrations of apparently distorted PO₄ tetrahedra.

The 871 cm⁻¹ band is certainly the bending vibration of OH⁻ groups.

The region of the stretching vibrations of OH⁻ groups between 3200 and 3600 cm⁻¹ shows a large and strong band at 3250 cm⁻¹, proving the existence of OH⁻ groups with hydrogens bonds and a sharp doublet at 3520 and 3540 cm⁻¹ due to free OH⁻ groups. This deduction is in good agreement with observations of MOORE and ARAKI (1973). Indeed there are two OH⁻ sites, located in 0(8) and 0(9) in the bjarebyite structure.

Following MOORE and ARAKI (1973), $0(9) = \text{OH}^-$ forms a hydrogen bond with $0(5)$, the distance being 2.60 Å and that appears in the IR spectrum at 3250 cm^{-1} . On the other hand the doublet is the stretching vibrations of OH^- groups located in $0(8)$ separated from $0(1)$ by a distance of 3.65 Å, too long to allow a hydrogen bond.

Conclusions

Bjarebyite, described in this paper, is to be added to the exceptionally long list of phosphate minerals occurring in Buranga mine. The new mineral is interesting and furnishes details about the geochemistry of this pegmatite.

From a geochemical point of view the presence of barium in the Buranga pegmatite is of some importance. In addition to the barium-rich bjarebyite, a barian arrojadite with 5.36 per cent BaO and another new barian phosphate containing 3.5 per cent BaO have been noted (VON KNORRING, 1972, 1973).

The paragenesis of bjarebyite in Buranga is also noteworthy. MOORE et al. (1973) described bjarebyite in Palermo from a complex association with the following phosphate minerals: amblygonite, augelite, childrenite, scorzalite and palermoite. This environment is nearly the same as that in Buranga. In this latter pegmatite it seems that Ca is more common than Sr, so the role of palermoite is taken by bertossaite.

Acknowledgments

The authors are indebted to Professor J. TOUSSAINT and M. VERMEIRE of the Institute of Crystallography, Univ. Liège for performing single crystal X-ray work.

We are very grateful to Professor P. TARTE of the Institute of Chemistry, Univ. Liège for recording IR spectra.

We wish to thank M. A. BERTOSSA for inviting one of us (O. v. K) to visit the Buranga pegmatite and collecting a large amount of samples. Visits to Leeds by one of us (A. M. F.) were supported by F.N.R.S. Grant, Belgium.
