Arithmetic properties of $\varphi(n)/\lambda(n)$ and the structure of the multiplicative group modulo n

William D. Banks, Florian Luca and Igor E. Shparlinski

Abstract. For a positive integer n, we let $\varphi(n)$ and $\lambda(n)$ denote the Euler function and the Carmichael function, respectively. We define $\xi(n)$ as the ratio $\varphi(n)/\lambda(n)$ and study various arithmetic properties of $\xi(n)$.

Mathematics Subject Classification (2000). 11A25.

Keywords. Euler function, Carmichael function.

1. Introduction and notation

Let $\varphi(n)$ denote the *Euler function*, which is defined as usual by

$$\varphi(n) = \#(\mathbb{Z}/n\mathbb{Z})^\times = \prod_{p^\nu \,\|\, n} p^{\nu-1}(p-1), \qquad n \geq 1.$$

The *Carmichael function* $\lambda(n)$ is defined for all $n \geq 1$ as the largest order of any element in the multiplicative group $(\mathbb{Z}/n\mathbb{Z})^\times$. More explicitly, for any prime power p^ν, one has

$$\lambda(p^\nu) = \begin{cases} p^{\nu-1}(p-1) & \text{if } p \geq 3 \text{ or } \nu \leq 2, \\ 2^{\nu-2} & \text{if } p = 2 \text{ and } \nu \geq 3, \end{cases}$$

and for an arbitrary integer $n \geq 2$,

$$\lambda(n) = \operatorname{lcm}\big(\lambda(p_1^{\nu_1}), \dots, \lambda(p_k^{\nu_k})\big),$$

where $n = p_1^{\nu_1} \dots p_k^{\nu_k}$ is the prime factorization of n. Clearly, $\lambda(1) = 1$.

Despite their many similarities, the functions $\varphi(n)$ and $\lambda(n)$ often exhibit remarkable differences in their arithmetic behavior, and a vast number of results about the growth rate and various arithmetical properties of $\varphi(n)$ and $\lambda(n)$ have been obtained; see for example [4], [5], [7], [8], [9], [11], [15]. In this paper, we consider the arithmetical function defined by

$$\xi(n) = \frac{\varphi(n)}{\lambda(n)}, \quad n \geq 1,$$

and we study some of its arithmetic properties.

In particular, letting $P(k)$ denote the largest prime factor of a positive integer k (with the convention that $P(1) = 1$), we study the behavior of $P(\xi(n))$. Our results imply that typically $\xi(n)$ is much "smoother" than a random integer k of the same size. To make this comparison, it is useful to recall that Theorem 2 of [9] implies that the estimate

$$\xi(n) = \exp\left(\log_2 n \log_3 n + C \log_2 n + o(\log_2 n)\right) \tag{1}$$

holds on a set of positive integers n of asymptotic density 1 with some absolute constant $C > 0$. Here, and in the sequel, for a real number $z > 0$ and a natural number ℓ, we write $\log_\ell z$ for the recursively defined function given by $\log_1 z = \max\{\log z, 1\}$, where $\log z$ denotes the natural logarithm of z, and $\log_\ell z = \max\{\log(\log_{\ell-1} z), 1\}$ for $\ell > 1$. When $\ell = 1$, we omit the subscript (however, we still assume that all the logarithms that appear below are at least 1). Of course, when z is sufficiently large, then $\log_\ell z$ is nothing more than the ℓ-fold composition of the natural logarithm evaluated at z.

We also use $\Omega(n)$ and $\omega(n)$ with their usual meanings: $\Omega(n)$ denotes the total number of prime divisors of $n > 1$ counted with multiplicity, while $\omega(n)$ is the number of distinct prime factors of $n > 1$; as usual, we put $\Omega(1) = \omega(1) = 0$. In this paper, we also study the functions $\Omega(\xi(n))$ and $\omega(\xi(n))$.

Observe that a prime p divides $\xi(n)$ if and only if the *p-Sylow subgroup* of the group $(\mathbb{Z}/n\mathbb{Z})^\times$ is *not* cyclic. Thus, $P(\xi(n))$ and $\omega(\xi(n))$ can be viewed as measures of "non-cyclicity" of this group. In particular, $\omega(\xi(n))$ is the number of non-cyclic Sylow subgroups of $(\mathbb{Z}/n\mathbb{Z})^\times$.

We also remark that any prime $p \mid \xi(n)$ has that property that $p^2 \mid \varphi(n)$. Thus, while studying the prime factors of $\xi(n)$, one is naturally lead to an associated question concerning the difference $\Omega(\varphi(n)) - \omega(\varphi(n))$, a question that we address here as well.

As usual, for a large number x, $\pi(x)$ denotes the number of primes $p \leq x$, and for positive integers a, k with $\gcd(a, k) = 1$, $\pi(x; k, a)$ denotes the number of primes $p \leq x$ with $p \equiv a \pmod{k}$.

We use the Vinogradov symbols $\gg$, $\ll$, $\asymp$ as well as the Landau symbols O and o with their usual meanings. The implied constants in the symbols O, $\gg$, $\ll$ and $\asymp$ are always absolute unless indicated otherwise.

Finally, we say that a certain property holds for "almost all" n if it holds for all $n \leq x$ with at most $o(x)$ exceptions, as $x \to \infty$.

Acknowledgements. The authors wish to thank Carl Pomerance for suggesting the statement of Theorem 9 and for some useful references. During the preparation of this paper, W. B. was supported in part by NSF grant DMS-0070628, F. L. was supported in part by grants SEP-CONACYT 37259-E and 37260-E, and I. S. was supported in part by ARC grant DP0211459.

2. Distribution of $P(\xi(n))$, $\omega(\xi(n))$ and $\Omega(\xi(n))$

In what follows, let us call a real-valued function $\varepsilon(x)$ *admissible* if

- $\varepsilon(x)$ is a decreasing function, with limit 0 as $x \to \infty$;
- $\varepsilon(x)\log_2 x$ is an increasing function, tending to ∞ as $x \to \infty$.

We begin with the following statement, which may be of independent interest.

Lemma 1. *For any admissible function $\varepsilon(x)$ and any prime $q \le \varepsilon(x)\log_2 x$, every positive integer $n \le x$ has at least $(\log_2 n)/2q$ distinct prime factors $p \equiv 1 \pmod q$, with at most $o(x)$ exceptions.*

Proof. Let $\omega(n,q)$ denote the number of distinct prime factors p of n such that $p \equiv 1 \pmod q$. For any real number $y \ge 1$ and integer $a \ge 1$, put

$$S(y,a) = \sum_{\substack{p \le y \\ p \equiv 1 \pmod a}} \frac{1}{p}. \tag{2}$$

It is known (see Theorem 1 in [18] or Lemma 6.3 in [17]) that

$$S(y,a) = \frac{\log_2 y}{\varphi(a)} + O(1). \tag{3}$$

In particular, the estimate

$$S(n,q) = \frac{\log_2 n}{q-1} + O(1) \gg \varepsilon(x)^{-1}$$

holds for all q in the stated range and all $n > x^{1/2}$, once x is sufficiently large. By the classical result of Turán [20], we also have that the estimate

$$\omega(n,q) = S(n,q) + O\left(S(n,q)^{2/3}\right)$$

holds for all n in the interval $x^{1/2} < n \le x$, with at most

$$O\left(xS(n,q)^{-1/6}\right) = O\left(x\,\varepsilon(x)^{1/6}\right) = o(x)$$

possible exceptions, and the result now follows. □

Lemma 2. *For real numbers $x \ge y > 1$ let*

$$\Xi(x,y) = \#\{n \le x : P(\xi(n)) > y\}.$$

Then,

$$\Xi(x,y) \ll \frac{x(\log_2 x)^2}{y \log y}.$$

Proof. If a prime q divides $\xi(n)$, then clearly $q^2 \mid \varphi(n)$. The upper bound

$$\#\{n \le x : \varphi(n) \equiv 0 \pmod{q^2}\} \ll \frac{x(\log_2 x)^2}{q^2}$$

is a special partial case of Lemma 2 of [5] (see also the proof of Theorem 7.1 in [4]). In particular,

$$\#\{n \le x : P(\xi(n)) = q\} \ll \frac{x(\log_2 x)^2}{q^2}. \tag{4}$$

It now follows that

$$\Xi(x,y) = \sum_{y<q\le x} \sum_{\substack{n \le x\\ P(\xi(n))=q}} 1 \ll \sum_{y<q\le x} \frac{x(\log_2 x)^2}{q^2}.$$

Using Abel summation, we estimate

$$\sum_{y<q\le x} \frac{1}{q^2} = \frac{\pi(x)}{x^2} - \frac{\pi(y)}{y^2} + 2\int_y^x \frac{\pi(t)}{t^3}\,dt \ll \frac{1}{x\log x} + \int_y^x \frac{1}{t^2 \log t}\,dt \ll \frac{1}{y \log y},$$

and the lemma follows. □

Theorem 1. *If $\varepsilon(x)$ is any admissible function, then the inequalities*

$$\varepsilon(n)\log_2 n \le P(\xi(n)) \le \frac{(\log_2 n)^2}{\varepsilon(n)\log_3 n}$$

hold for almost all positive integers n.

Proof. By the Prime Number Theorem, for all sufficiently large real numbers x there exists a prime q in the interval:

$$\varepsilon(x)\log_2 x < q \le 2\,\varepsilon(x)\log_2 x.$$

If n is an integer with two prime factors $p_1 \equiv p_2 \equiv 1 \pmod q$, then $q \mid \xi(n)$. By Lemma 1, we derive that

$$\sum_{\substack{x^{1/2}<n\le x\\ P(\xi(n))\ge \varepsilon(n)\log_2 n}} 1 \ge \sum_{\substack{x^{1/2}<n\le x\\ P(\xi(n))\ge q}} 1 \ge \sum_{\substack{x^{1/2}<n\le x\\ \omega(n,q)\ge 2}} 1 = x + o(x).$$

This proves the lower bound. The upper bound is a direct application of Lemma 2. □

We remark that the upper bound of Theorem 1 improves the corollary to Theorem 2 in [9].

Theorem 2. *As $x \to \infty$, we have*

$$(1+o(1))\, x \log_3 x \le \sum_{n\le x} \log P(\xi(n)) \le (2+o(1))\, x \log_3 x.$$

Proof. The above lower bound follows from the lower bound from Theorem 1. For the upper bound above, we write

$$\sum_{n\le x} \log P(\xi(n)) = \sum_{q\le x} \log q \sum_{\substack{n\le x\\ P(\xi(n))=q}} 1.$$

For $q \le y$, we trivially have

$$\sum_{q\le y} \log q \sum_{\substack{n\le x\\ P(\xi(n))=q}} 1 \le \log y \sum_{q\le y} \sum_{\substack{n\le x\\ P(\xi(n))=q}} 1 \le \log y \sum_{n\le x} 1 \le x \log y,$$

while for $q > y$, we have, by (4):

$$\sum_{y<q\le x} \log q \sum_{\substack{n\le x\\ P(\xi(n))=q}} 1 \ll x(\log_2 x)^2 \sum_{y<q\le x} \frac{\log q}{q^2} \ll x y^{-1} (\log_2 x)^2,$$

where we have used Abel summation to estimate

$$\begin{aligned}\sum_{y<q\le x} \frac{\log q}{q^2} &= \pi(x)\frac{\log x}{x^2} - \pi(y)\frac{\log y}{y^2} - \int_y^x \pi(t)\left(\frac{1}{t^3} - \frac{2\log t}{t^3}\right) dt\\ &\ll x^{-1} + \int_y^x t^{-2}\, dt \ll y^{-1}.\end{aligned}$$

Setting $y = (\log_2 x)^2$, we obtain the desired upper bound. □

Theorem 3. *As $x \to \infty$, we have*

$$\sum_{n\le x} P(\xi(n)) \asymp x(\log_2 x)^3.$$

Proof. Let $y = (\log_2 x)^3$, $z = \exp((\log x)^{1/2})$ and $w = \exp((\log x)^{2/3})$. We also put $v = z^6$. In what follows, x is taken to be arbitrarily large.

Taking $A = 5/2$, $\varepsilon = 1/2$, and $\delta = 1/15$ in the statement of Theorem 2.1 of [1], we see that there exists an absolute constant $D \geq 0$ and a set $\mathcal{D}$ of cardinality $\#\mathcal{D} \leq D$, with $\min\{m : m \in \mathcal{D}\} \geq \log v = 6(\log x)^{1/2}$, such that the inequality

$$\pi(t; d, 1) \geq \frac{\pi(t)}{2\varphi(d)} \tag{5}$$

holds for all positive reals t provided that $1 \leq d \leq \min\{tv^{-2/3}, z^2\}$ and that d is not divisible by any element of $\mathcal{D}$. Note that if x is sufficiently large and $t \geq w$, then $tv^{-2/3} \geq wv^{-2/3} \geq z^2$.

Letting $\mathcal{Q}$ denote the set of primes $q \in [y, z]\backslash\mathcal{D}$, we therefore see that the lower bound (5) holds for all $t \in [w, x]$ and all integers $d \in [1, z^2]$ whose prime factors all lie in $\mathcal{Q}$. Together with the Brun–Titchmarsh theorem (see for example Theorem 3.7 in Chapter 3 of [12]), we conclude that

$$\pi(t; d, 1) \asymp \frac{\pi(t)}{\varphi(d)}$$

holds uniformly for all $t \in [w, x]$ and all integers d of the form $d = q$ or $d = q_1 q_2$ composed of one or two (not necessarily distinct) primes from $\mathcal{Q}$. Moreover, for any sufficiently large constant $\gamma > 1$, we also have

$$\pi(t; d, 1) - \pi(t/\gamma; d, 1) \asymp \frac{\pi(t)}{\varphi(d)} \tag{6}$$

under the same conditions.

We now let

$$k = \left\lceil \frac{\log w}{\log \gamma} \right\rceil \quad \text{and} \quad K = \left\lfloor \frac{\log x}{2\log \gamma} \right\rfloor - 1.$$

For any prime $q \in \mathcal{Q}$, we have, by (6):

$$\sum_{\substack{w < p \leq x^{1/2} \\ p \equiv 1 \pmod q}} \frac{1}{p} \geq \sum_{j=k}^{K} \frac{\pi(\gamma^{j+1}; d, 1) - \pi(\gamma^j; d, 1)}{\gamma^{j+1}} \gg \frac{1}{q} \sum_{j=k}^{K} \frac{1}{j} \gg \frac{\log_2 x}{q}.$$

On the other hand, the upper bound (3.1) in [7] (see also Lemma 1 of [5]) provides an upper bound of the same size as the above lower bound. Consequently,

$$\sum_{\substack{w < p \leq x^{1/2} \\ p \equiv 1 \pmod q}} \frac{1}{p} \asymp \frac{\log_2 x}{q}. \tag{7}$$

We now fix a prime number q in $\mathcal{Q}$. We denote by $N(x,q)$ the number of integers $n \le x$ for which there exists a unique representation of the form $n = p_1p_2m$ for some integer m and two primes $w < p_1 < p_2 \le x^{1/2}$ with $p_1 \equiv p_2 \equiv 1 \pmod q$ and such that q is the only prime in $\mathcal{Q}$ dividing $\gcd(p_1-1, p_2-1)$. We then have

$$N(x,q) \ge T_0(x,q) - T_1(x,q) - T_2(x,q) - T_3(x,q),$$

where

- $T_0(x,q)$ is the total number of ordered triples (p_1, p_2, m) with primes $w < p_1 < p_2 \le x^{1/2}$, $p_1 \equiv p_2 \equiv 1 \pmod q$, and an integer $m \le x/p_1p_2$. Therefore, using (7), we obtain that

$$\begin{aligned}
T_0(x,q) &\gg x \sum_{\substack{w<p_1<p_2\le x^{1/2}\\ p_1\equiv p_2\equiv 1 \pmod q}} \frac{1}{p_1p_2}\\
&= \frac{x}{2}\Bigg(\sum_{\substack{w<p\le x^{1/2}\\ p\equiv 1 \pmod q}} \frac{1}{p}\Bigg)^2 - \frac{x}{2}\sum_{\substack{w<p\le x^{1/2}\\ p\equiv 1 \pmod q}} \frac{1}{p^2}\\
&\gg \frac{x}{2}\left(\frac{\log_2 x}{q}\right)^2 - \frac{x}{2q}\sum_{\substack{w<p\le x^{1/2}\\ p\equiv 1 \pmod q}} \frac{1}{p}\\
&= \frac{x(\log_2 x)^2}{2q^2} + O\left(\frac{x\log_2 x}{q^2}\right) \gg \frac{x(\log_2 x)^2}{q^2}.
\end{aligned}$$

- $T_1(x,q)$ is the number of triples (p_1, p_2, m) as above for which there exists another prime $\ell \in \mathcal{Q}$, $\ell \ne q$, such that $p_1 \equiv p_2 \equiv 1 \pmod \ell$. Then, by (7), we have that

$$\begin{aligned}
T_1(x,q) &\ll x \sum_{\substack{\ell\in\mathcal{Q}\\ \ell\ne q}} \sum_{\substack{w<p_1<p_2\le x^{1/2}\\ p_1\equiv p_2\equiv 1 \pmod{q\ell}}} \frac{1}{p_1p_2} \le x\sum_{\ell\in\mathcal{Q}}\Bigg(\sum_{\substack{w<p<x^{1/2}\\ p\equiv 1 \pmod{q\ell}}} \frac{1}{p}\Bigg)^2\\
&\ll x\sum_{\ell\in\mathcal{Q}} \frac{(\log_2 x)^2}{q^2\ell^2} \ll \frac{x(\log_2 x)^2}{q^2}\sum_{\ell>y}\frac{1}{\ell^2}\\
&\ll \frac{x(\log_2 x)^2}{q^2 y\log y} = o\left(\frac{x(\log_2 x)^2}{q^2}\right).
\end{aligned}$$

- $T_2(x,q)$ is the number of triples (p_1, p_2, m) as above for which there exists another prime p_3, $w < p_3 \le x^{1/2}$, which divides m, and for some prime $\ell \in \mathcal{Q}$

(possibly $\ell = q$) one has $p_3 \equiv 1 \pmod{\ell}$, and either $p_1 \equiv 1 \pmod{\ell}$, or $p_2 \equiv 1 \pmod{\ell}$. Therefore, by (7), we see that

$$\begin{aligned} T_2(x,q) &\ll x \sum_{\ell \in \mathcal{Q}} \sum_{\substack{w<p_1,p_2 \le x^{1/2} \\ w<p_3 \le x^{1/2} \\ p_1 \equiv p_2 \equiv 1 \pmod{q} \\ p_3 \equiv p_2 \equiv 1 \pmod{\ell}}} \frac{1}{p_1 p_2 p_3} \\ &\ll x \sum_{\ell \in \mathcal{Q}} \sum_{\substack{w<p_1 \le x^{1/2} \\ p_1 \equiv 1 \pmod{q}}} \frac{1}{p_1} \sum_{\substack{w<p_2 \le x^{1/2} \\ p_2 \equiv 1 \pmod{q\ell}}} \frac{1}{p_2} \sum_{\substack{w<p_3 \le x^{1/2} \\ p_3 \equiv 1 \pmod{\ell}}} \frac{1}{p_3} \\ &\ll x(\log_2 x)^3 \sum_{y \le \ell \le z} \frac{1}{q^2 \ell^2} \ll \frac{x(\log_2 x)^3}{q^2 y \log y} = o\left(\frac{x(\log_2 x)^2}{q^2}\right). \end{aligned}$$

- $T_3(x,q)$ is the number of triples (p_1, p_2, m) as above for which there exists another triple (r_1, r_2, k) with primes $w \le r_1 < r_2 \le x^{1/2}$ such that $r_1 \equiv r_2 \equiv 1 \pmod{\ell}$ for some $\ell \in \mathcal{Q}$, and $p_1 p_2 m = r_1 r_2 k$. Applying (7) once again, we obtain that

$$\begin{aligned} T_3(x,q) &\ll x \sum_{\ell \in \mathcal{Q}} \sum_{\substack{w<p_1<p_2 \le x^{1/2} \\ p_1 \equiv p_2 \equiv 1 \pmod{q}}} \frac{1}{p_1 p_2} \sum_{\substack{w<r_1<r_2 \le x^{1/2} \\ r_1 \equiv r_2 \equiv 1 \pmod{\ell}}} \frac{1}{r_1 r_2} \\ &\ll x(\log_2 x)^4 \sum_{y \le \ell \le z} \frac{1}{q^2 \ell^2} \ll \frac{x(\log_2 x)^4}{q^2 y \log y} = o\left(\frac{x(\log_2 x)^2}{q^2}\right). \end{aligned}$$

Consequently, we have

$$N(x,q) \ge T_0(x,q) - T_1(x,q) - T_2(x,q) - T_3(x,q) \gg \frac{x(\log_2 x)^2}{q^2}.$$

We note that $P(\xi(n)) \ge q$ for all $n \in N(x,q)$ and that the sets $N(x,q)$ are disjoint for different choices of $q \in \mathcal{Q}$. Thus,

$$\begin{aligned} \sum_{n \le x} P(\xi(n)) &\gg \sum_{q \in \mathcal{Q}} q\,\#N(x,q) \gg x(\log_2 x)^2 \sum_{q \in \mathcal{Q}} \frac{1}{q} \\ &\ge x(\log_2 x)^2 \Big(\sum_{y \le q \le z} \frac{1}{q} - \frac{D}{6(\log x)^{1/2}} \Big) \\ &\gg x(\log_2 x)^2 (\log_2 z - \log_2 y + o(1)) \gg x(\log_2 x)^3. \end{aligned}$$

To prove the upper bound, we simply use (4) to derive that

$$\sum_{n\le x} P(\xi(n)) \le \sum_{q\le x} q \sum_{\substack{n\le x\\ P(\xi(n))=q}} 1 \ll x(\log_2 x)^2 \sum_{q\le x}\frac{1}{q} \ll x(\log_2 x)^3.$$

This completes the proof. □

Concerning the minimal order of $P(\xi(n))$, little need be said; clearly $P(\xi(n)) \ge 1$ for all $n \ge 1$, and equality holds if and only if $n = 2, 4, p^\nu$ or $2p^\nu$ for some odd prime p and $\nu \ge 1$. As for the maximal order, we have the following:

Theorem 4. *The inequality*

$$P(\xi(n)) \le \frac{(3n+1)^{1/2}-2}{6}$$

holds for all $n \ge 276$, and the inequality

$$P(\xi(n)) \gg n^{0.3335}$$

holds for infinitely many n.

Proof. For n in the range $276 \le n \le 579$, the upper bound can be verified case by case; hence, we assume that $n \ge 580$ in what follows. Without loss of generality, we may further assume that $q = P(\xi(n)) > 3$, since

$$3 \le \frac{(3n+1)^{1/2}-2}{6} \quad \text{holds for all } n \ge 133.$$

If $P(\xi(n)) = q$, then either n has a prime divisor $p \equiv 1 \pmod q$ and $q^2p \mid n$, or n has two distinct prime divisors $p_1 \equiv p_2 \equiv 1 \pmod q$. In the first case, we see that

$$q < (q^2p/2)^{1/3} \le (n/2)^{1/3} \le \frac{(3n+1)^{1/2}-2}{6},$$

the last inequality being valid for all $n \ge 580$. In the second case, suppose $p_1 = aq+1$ and $p_2 = bq+1$, where $a < b$ are distinct even integers. Now if $2q+1$ is prime, then $4q+1$ is divisible by 3; thus, we must have $a \ge 2$, $b \ge 6$. Then

$$(2q+1)(6q+1) \le (aq+1)(bq+1) = p_1p_2 \le n,$$

and we obtain the stated upper bound.

To establish the lower bound, we recall the result of Fouvry [10], which asserts that for all large x, the set $\mathcal{Q}$ of primes p in the interval $x^{1/2} \le p \le x$ and satisfying $P(p-1) \gg p^{0.667}$ is of cardinality $\#\mathcal{Q} \gg x/\log x$. We also recall that, by Brun's method (see Theorem 2.2 in [12]), for any integer m, the number of primes of the form $p = mq + 1 \le x$ for some other prime q is

$$O\left(\frac{x}{\varphi(m)(\log(x/m))^2}\right) = O\left(\frac{x}{\varphi(m)(\log x)^2}\right)$$

provided that $m < x^{1/2}$. Summing up the above inequalities over all positive integers $m \le \log_2 x$, we see that

$$\#\{p \le x : P(p-1) \ge x/\log_2 x\} \ll \frac{x}{\log^2 x} \sum_{m<\log x} \frac{1}{\varphi(m)} \ll \frac{x \log_2 x}{\log^2 x} = o(\mathcal{Q}).$$

Thus, most of the primes p in $\mathcal{Q}$ in the interval have $q = P(p-1) < x/\log_2 x$, and therefore there exist two primes $p_1, p_2 \in \mathcal{Q}$ with the same value of $P(p_1 - 1) = P(p_2-1) = q$. With $n = p_1 p_2$, we see that $P(\xi(n)) \ge q \gg \max\left\{p_1^{0.667}, p_2^{0.667}\right\} \gg n^{0.3335}$. $\square$

As is clear from the proof, the upper bound of Theorem 4 is tight under the prime k-tuplet conjecture of Hardy and Littlewood (see, for example, [3]). We also remark that the trivial upper bound $P(\xi(n)) \le n^{1/2}$ holds for all $n \ge 1$.

Unfortunately, our method of proof for the lower bound of Theorem 4 can not be combined with the more recent results of [2], since the set of primes considered there is too thin.

Theorem 5. *The inequalities*

$$\Omega(\xi(n)) = (1 + o(1)) \log_2 n \log_4 n \quad \textit{and} \quad \frac{\log_2 n}{(\log_3 n)^2} \ll \omega(\xi(n)) \ll \log_2 n$$

hold for almost all positive integers n.

Proof. We start with $\Omega(\xi(n))$ and first turn our attention to the upper bound. Let x be a large positive real number, and let $\mathcal{A}_1$ be the set of all positive integers n in the interval $[x/\log x,\ x]$. Clearly, $\mathcal{A}_1$ contains all but $o(x)$ positive integers $n \le x$. Let $\mathcal{A}_2$ be the set of those integers $n \in \mathcal{A}_1$ for which $P(\xi(n)) \le (\log_2 x)^2$; by Theorem 1, $\mathcal{A}_2$ contains all but $o(x)$ positive integers $n \le x$. Let $y = (\log_2 x)^2$. For any positive integer m, we write

$$\omega_y(m) = \sum_{\substack{p<y \\ p \mid m}} 1 \quad \text{and} \quad \Omega_y(m) = \sum_{\substack{p<y \\ p^\nu \parallel m}} \nu.$$

Thus, the inequality $\Omega(\xi(n)) \le \Omega_y(\varphi(n))$ holds for all $n \in \mathcal{A}_2$. The argument on page 349 in [8] shows that

$$\sum_{n \le x} \left|\Omega_y(\varphi(n)) - \log_2 x \log_2 y\right|^2 \ll x \log_2 x (\log_2 y)^2. \tag{8}$$

Now let $\varepsilon_1(x) = (\log_2 x)^{-1/3}$, and let $\mathcal{B}$ be the set of those $n \le x$ such that

$$\Omega_y(\varphi(n)) > (1 + \varepsilon_1(x)) \log_2 x \log_2 y.$$

Using (8), it follows that

$$\#\mathcal{B} \ll \frac{x}{\varepsilon_1(x)^2 \log_2 x} = o(x).$$

The set $\mathcal{A}_3 = \mathcal{A}_2 \backslash \mathcal{B}$ contains all but $o(x)$ positive integers $n \le x$, and for each $n \in \mathcal{A}_3$ we have

$$\Omega(\xi(n)) \le \Omega_y(\varphi(n)) \le (1 + \varepsilon_1(x)) \log_2 x \log_2 y = (1 + o(1)) \log_2 x \log_4 x. \quad (9)$$

Since $n \ge x/\log x$ for all $n \in \mathcal{A}_3$, this shows that

$$\Omega(\xi(n)) \le (1 + o(1)) \log_2 n \log_4 n$$

for almost all positive integers n.

Next we turn to the lower bound for $\Omega(\xi(n))$. As before, let x be a large real number, and put $\varepsilon_2(x) = (\log_3 x)^{-1/3}$ and $Q = (\log_2 x)^{1/2}$. For natural numbers n and q, we again write $\omega(n, q)$ for the number of prime factors p of n that are congruent to 1 modulo q. For a prime $q \le Q$ we define the sets

$$\mathcal{C}_q = \left\{ n \le x : \omega(n, q) \le (1 - \varepsilon_2(x)) \frac{\log_2 x}{\varphi(q)} \right\},$$

and

$$\mathcal{C} = \bigcup_{q \le Q} \mathcal{C}_q.$$

We claim that $\#\mathcal{C} = o(x)$ as $x \to \infty$. Indeed, for a fixed prime $q \le Q$, by a result of Turán [20] (see also (1.2) of [17]), we have

$$\#\mathcal{C}_q \ll \frac{xq}{\varepsilon_2^2(x) \log_2 x} \ll \frac{x(\log_3 x)^{2/3}}{\log_2 x} q.$$

Therefore,

$$\#\mathcal{C} \le \sum_{q \le Q} \#\mathcal{C}_q \ll \frac{x(\log_3 x)^{2/3}}{\log_2 x} \sum_{q \le (\log_2 x)^{1/2}} q \ll \frac{x}{(\log_3 x)^{1/3}} = o(x).$$

Now let $\mathcal{D}$ be the set of those positive integers $n \le x$ not lying in $\mathcal{C}$. Then for each

$n \in \mathcal{D}$, one has

$$\begin{aligned}\Omega(\xi(n)) &\geq \sum_{q\leq Q}(\omega(n,q)-1) = \sum_{q\leq Q}\omega(n,q) - \pi(Q)\\ &\geq (1-\varepsilon_2(x))\log_2 x \sum_{q\leq Q}\frac{1}{\varphi(q)} - \pi(Q)\\ &\geq (1-\varepsilon_2(x))\log_2 x \sum_{q\leq Q}\frac{1}{q} - \pi(Q)\\ &\geq (1+o(1))\log_2 x \log_4 x \geq (1+o(1))\log_2 n \log_4 n.\end{aligned}$$

This completes the proof of the normal order of $\Omega(\xi(n))$.

We now turn our attention to $\omega(\xi(n))$ and start with the lower bound. Again, let x be a large positive real number, and let $\varepsilon_3(x)$ be any admissible function. Let q be a prime number and let $\nu_q(m)$ denote the largest power of q dividing a natural number m. It suffices to show that there exists a constant c_1 such that for all but $o(x)$ positive integers $n \leq x$, the estimate

$$\nu_q(\xi(n)) \geq \varepsilon_3(x)\log_2 x, \tag{10}$$

holds simultaneously for all primes $q \leq c_1 \log_2 x/\log_3 x$.

Let us define

$$\mathcal{W}_q = \left\{n \leq x : \omega(n,q) < \tfrac{\log_2 x}{2\varphi(q)}\right\}.$$

By the result of Turán mentioned above, we have $\#\mathcal{W}_q \ll xq/\log_2 x$; summing up these estimates for all $q \leq (\log_3 x)^{1/2}$, we see that

$$\sum_{q\leq(\log_3 x)^{1/2}} \#\mathcal{W}_q \ll \frac{x}{\log_2 x}\sum_{q\leq(\log_3 x)^{1/2}} q \ll \frac{x\log_3 x}{\log_2 x \log_4 x} = o(x).$$

We also note that for $q \leq (\log_3 x)^{1/2}$, we have

$$\frac{\log_2 x}{2\varphi(q)} \gg \frac{\log_2 x}{(\log_3 x)^{1/2}}$$

which establishes (10) for q in this small range if $\varepsilon_3(x) \leq (\log_3 x)^{-1/2}$, which we now assume.

Next we consider the case in which $q > (\log_3 x)^{1/2}$.

Let us denote by $\omega_y(n)$ the number of prime factors p of n with $p \leq y$. Let $\mathcal{N}$ be the set of integers $x^{1/2} \leq n \leq x$ for which

$$\omega_y(n) = \log_2 y + O((\log_2 y)^{2/3})$$

holds simultaneously for $y = \exp((\log x)^{1/2})$ and for $y = x$. By [20], we have that $\#\mathcal{N} = x + o(x)$.

Let $\mathcal{E}_q$ be the set of $n \in \mathcal{N}$ such that $p^2 \mid n$ for some $p \equiv 1 \pmod q$ and let $\mathcal{E}$ be the union of all $\mathcal{E}_q$ for $q > (\log_3 x)^{1/2}$. Clearly,

$$\#\mathcal{E}_q \ll \sum_{p\equiv 1 \pmod q} \frac{x}{p^2} \le \frac{x}{q^2}\sum_{t\ge 1}\frac{1}{t^2} \ll \frac{x}{q^2},$$

and therefore

$$\#\mathcal{E} \le \sum_{q>(\log_3 x)^{1/2}} \#\mathcal{E}_q \ll x \sum_{q>(\log_3 x)^{1/2}} \frac{1}{q^2} = o\left(\frac{x}{(\log_3 x)^{1/2}}\right) = o(x).$$

For a fixed positive integer k and primes $p_1 \equiv \cdots \equiv p_k \equiv 1 \pmod q$, let $\mathcal{N}_{k,q}(p_1, \dots, p_k)$ be the set of integers $n \in \mathcal{N}\backslash\mathcal{E}$ such that $n = p_1 \dots p_k m$ holds with some integer m with $\omega(m, q) = 0$.

We first show that if $k \le 0.5 \log_2 x$, then $\mathcal{N}_{k,q}(p_1, \dots, p_k)$ is empty unless

$$\frac{x}{p_1 \cdots p_k} \ge z, \tag{11}$$

where $z = \exp((\log x)^{1/2})$. Indeed, in the opposite case, we see that for $n \in \mathcal{N}_{k,q}(p_1, \dots, p_k)$,

$$\omega(n) \le k + \omega(m) \le k + \omega_z(n) \le 0.5 \log_2 x + O\left((\log_2 x)^{1/2}\right),$$

which is impossible because $\omega(n) \sim \log_2 n \sim \log_2 x$ for $n \in \mathcal{N}$.

We now have

$$\#\mathcal{N}_{k,q}(p_1, \dots, p_k) \le \sum_{\substack{m\le x/(p_1\dots p_k)\\ q\nmid\varphi(m)}} 1. \tag{12}$$

It has been shown in the proof of Theorem 4.1 of [7] that there exists an absolute constant $c_2 > 0$ such that the upper bound

$$\sum_{\substack{m\le t\\ q\nmid\varphi(m)}} 1 \ll t \exp\left(-c_2 S(t, q)\right)$$

holds uniformly when $\log t > q$, where $S(t, q)$ is given by (2). By Theorem 3.4 of [7], we know that the lower bound

$$S(t, q) \gg \frac{\log_2 t}{q}$$

holds provided that $q < \log t$. Thus, assuming (11), and remarking that $\log z = (\log x)^{1/2} > q$, we derive from (12) that the estimate

$$\#\mathcal{N}_{k,q}(p_1,\dots,p_k) \ll \frac{x}{p_1\dots p_k}\exp\left(-c_3\frac{\log_2 x}{q}\right)$$

holds with some absolute constant $c_3 > 0$.

Therefore, the set $\mathcal{N}_{k,q}$ consisting of all integers n in $\mathcal{N}\backslash\mathcal{E}$ that belong to at least one of the sets $\mathcal{N}_{k,q}(p_1,\dots,p_k)$, for fixed k and q, has cardinality at most

$$\begin{aligned}\#\mathcal{N}_{k,q} &= \frac{1}{k!}\sum_{\substack{p_1<x\\ p_1\equiv 1 \pmod q}}\cdots\sum_{\substack{p_k<x\\ p_k\equiv 1 \pmod q}} \#\mathcal{N}_{k,q}(p_1,\dots,p_k)\\ &\le \frac{1}{k!}\sum_{\substack{p_1<x\\ p_1\equiv 1 \pmod q}}\cdots\sum_{\substack{p_k<x\\ p_k\equiv 1 \pmod q}} \frac{x}{p_1\dots p_k}\exp\left(-c_3\frac{\log_2 x}{q}\right)\\ &\le \frac{x}{k!}\exp\left(-c_3\frac{\log_2 x}{q}\right)S(x,q)^k.\end{aligned}$$

Put $K_q = \varepsilon_3(x)(\log_2 x)/q$. Recalling the bound (3) and using the Stirling formula, we obtain

$$\begin{aligned}\sum_{k\le K_q}\#\mathcal{N}_{k,q} &\ll x\exp\left(-c_3\frac{\log_2 x}{q}\right)\sum_{k\le K_q}\frac{(2\log_2 x)^k}{q^k k!}\\ &\ll x\exp\left(-c_3\frac{\log_2 x}{q}\right)\sum_{k\le K_q}\left(\frac{6\log_2 x}{qk}\right)^k.\end{aligned}$$

Furthermore, we derive

$$\begin{aligned}\sum_{k\le K_q}\left(\frac{6\log_2 x}{qk}\right)^k &\ll \sum_{0\le i\le \log K_q}\ \sum_{K_q e^{-i-1}\le k\le K_q e^{-i}}\left(\frac{6e^{i+1}\log_2 x}{qK_q}\right)^k\\ &= \sum_{0\le i\le \log K_q}\ \sum_{K_q e^{-i-1}\le k\le K_q e^{-i}}\left(6\varepsilon_3^{-1}(x)e^{i+1}\right)^k\\ &\ll \sum_{0\le i\le \log K_q}\left(6\varepsilon_3^{-1}(x)e^{i+1}\right)^{K_q e^{-i}}\\ &\ll \exp\left(c_4 K_q\log\left(\varepsilon_3^{-1}(x)\right)\right)\end{aligned}$$

for some constant c_4. Therefore, for an appropriate constant c_1,

$$\begin{aligned}\sum_{q \le c_1 \log_2 x/\log_3 x} \sum_{k \le K_q} \# \mathcal{N}_{k,q} &\ll x \sum_{q \le c_1 \log_2 x/\log_3 x} \exp\left(-c_3 \frac{\log_2 x}{q} + c_4 K_q \log\left(\varepsilon_3^{-1}(x)\right)\right) \\ &\ll x \sum_{q \le c_1 \log_2 x/\log_3 x} \exp\left(-0.5 c_3 \frac{\log_2 x}{q}\right) = o(x)\end{aligned}$$

provided that x is large enough. Clearly, the inequality (10) implies the desired lower bound on $\omega(\xi(n))$.

We now prove the upper bound on $\omega(\xi(n))$. By (1), we know that the inequality

$$\log(\xi(n)) \ll \log_2 n \log_3 n \tag{13}$$

holds on a set of positive integers 1 of asymptotic density 1. The upper bound on $\omega(\xi(n))$ claimed by our Theorem 5 follows now from inequality (13) above combined with the classical estimate

$$\omega(\xi(n)) \ll \frac{\log \xi(n)}{\log_2 \xi(n)},$$

which concludes the proof. □

It is easy to see that Theorem 5 implies that for some constant $c_5 > 0$, the bound

$$\tau(\xi(n)) \ge 2^{\omega(\xi(n))} \gg \exp\left(c_5 \frac{\log_2 n}{(\log_3 n)^2}\right)$$

holds for almost all positive integers n, where, as usual, $\tau(k)$ denotes the number of divisors of an integer $k \ge 1$.

It is also clear that for any positive integer n

$$\omega(\xi(n)) \le \omega(\varphi(n)) \ll \frac{\log \varphi(n)}{\log_2 \varphi(n)} \ll \frac{\log n}{\log_2 n}$$

and

$$\Omega(\xi(n)) \ll \Omega(\varphi(n)) \ll \log \varphi(n) \ll \log n.$$

Theorem 6. *The inequalities*

$$\Omega(\xi(n)) \gg \log n \quad \textit{and} \quad \omega(\xi(n)) \gg \frac{\log n}{\log_2 n}$$

hold for infinitely many positive integers n.

Proof. Let k be a sufficiently large integer, and then let p_1 and p_2 be the first two primes in the arithmetic progression $1 \pmod{2^k}$. By Linnik's Theorem, in the form given by Heath-Brown [13], we know that $\max\{p_1, p_2\} \ll 2^{11k/2}$, With $n = p_1 p_2$, we have that $2^k \mid \xi(n)$; therefore $\Omega(\xi(n)) \ge k \gg \log n$. Finally, let y be large and let $M = \prod_{p<y} p$. By the Prime Number Theorem, we have $\log M = (1 + o(1))y$. Let p_1 and p_2 be the first two primes in the arithmetic progression $1 \pmod{M}$. We again have that $\max\{p_1, p_2\} \ll M^{11/2}$, and with $n = p_1 p_2$ we have that $M \mid \xi(n)$. Thus,

$$\omega(\xi(n)) \gg \omega(M) = \pi(y) \gg \frac{\log M}{\log_2 M} \gg \frac{\log n}{\log_2 n},$$

which finishes the proof. □

3. Average q-adic norm and order of $\varphi(n)$

Let q be a prime, and let $|m|_q$ be the q-adic norm of m, that is, $|m|_q = q^{-\nu_q(m)}$ where, as before, $\nu_q(m)$ is the largest power of q dividing m. In this section, we address the average value of $|\varphi(n)|_q$ and $\nu_q(\varphi(n))$.

Recall that an arithmetic function $f(n)$ is said to be *multiplicative* if $f(nm) = f(n)f(m)$ for any integers n and m with $\gcd(n, m) = 1$. Accordingly, if $f(nm) = f(n) + f(m)$ for any integers n and m with $\gcd(n, m) = 1$ then $f(n)$ is called *additive*.

In particular, $\nu_q(\varphi(n))$ is an additive function. Thus, $|\varphi(n)|_q$ is a bounded multiplicative function, and therefore it is natural that our principal tool is the following theorem of Wirsing [21].

Lemma 3. *Assume that a real-valued multiplicative function $f(n)$ satisfies the following conditions:*

- $f(n) \ge 0$, $n = 1, 2, \ldots$;
- $f(p^\nu) \le ab^\nu$, $\nu = 2, 3, \ldots$, *for some constants* $a, b > 0$ *with* $b < 2$;
- *there exists a constant* $\tau > 0$ *such that*

$$\sum_{p \le x} f(p) = (\tau + o(1)) \frac{x}{\log x}.$$

Then, for any $x \ge 0$,

$$\sum_{n \le x} f(n) = \left(\frac{1}{e^{\gamma\tau}\Gamma(\tau)} + o(1) \right) \frac{x}{\log x} \prod_{p \le x} \left(\sum_{\nu=0}^{\infty} \frac{f(p^\nu)}{p^\nu} \right),$$

where γ is the Euler constant, and

$$\Gamma(s) = \int_0^\infty e^{-t} t^{s-1}\, dt$$

is the Γ-function.

Lemma 4. *For any fixed prime q,*

$$\prod_{p \le x} \left(1 + \frac{|p-1|_q}{p-1}\right) = \big(\eta_q + o(1)\big)\, (\log_2 x)^{\alpha_q},$$

where $\alpha_q = (q^2 - q - 1)/(q^2 - 1)$, and η_q is a constant depending only on q.

Proof. We have

$$\log\left(1 + \frac{|p-1|_q}{p-1}\right) = \frac{|p-1|_q}{p} + O\left(\frac{|p-1|_q}{p^2}\right),$$

therefore the series

$$\zeta_q = \sum_p \left| \log\left(1 + \frac{|p-1|_q}{p-1}\right) - \frac{|p-1|_q}{p} \right|$$

converges absolutely. Hence, it is enough to show that

$$\sum_{p \le x} \frac{|p-1|_q}{p} = \alpha_q \log_2 x + \beta_q + o(1) \tag{14}$$

holds with some constant β_q.

We have:

$$\begin{aligned} \sum_{p \le x} \frac{|p-1|_q}{p} &= \sum_{k=0}^{\infty} \Bigg(\sum_{\substack{p \le x \\ p \equiv 1 \pmod{q^k}}} \frac{q^{-k}}{p} - \sum_{\substack{p \le x \\ p \equiv 1 \pmod{q^{k+1}}}} \frac{q^{-k}}{p} \Bigg) \\ &= S(x, 1) - (q-1) \sum_{k=1}^{\infty} q^{-k} S(x, q^k), \end{aligned} \tag{15}$$

where, as before, $S(x, q^k)$ is given by (2).

We write K for the largest positive integer such that $q^K \le \log_2 x$; thus, $K \asymp \log_3 x$. Using the classical *Page bound* (see Chapter 20 of [6]) and partial summation (see a remark in Chapter 22 of [6]), we have

$$\pi(t; q^k, 1) = \frac{t}{(q-1)q^{k-1} \log t} + O\left(\frac{t}{q^k (\log t)^2}\right) \tag{16}$$

for all positive integers $k \le K$ and real $t \ge e^K$.

Therefore, using the same partial summation arguments as in the proof of Theorem 1 of [18] (see also Lemma 6.3 of [17]), and using (16) in the appropriate place (starting with the value of $t \ge e^K$), we derive that for every $k \le K$,

$$S(x, q^k) = \frac{\log_2 x}{(q-1)q^{k-1}} + A_{k,q} + O\left(\frac{1}{(\log x)^{1/2}}\right), \tag{17}$$

for some constants $A_{k,q}$ depending only on k and q. Moreover, by Theorem 1 of [18] or Lemma 6.3 of [17], $A_{k,q} = O(1)$ uniformly for q and $k = 0, 1, \ldots$ (see (3)).

For $k \ge K$, we use the fact that

$$S(x, q^k) \ll \frac{\log_2 x}{(q-1)q^{k-1}} \tag{18}$$

(see the bound (3.1) in [7] and also Lemma 1 of [5]). Define

$$\beta_q = A_{k,0} - (q-1)\sum_{k\ge1} \frac{A_{k,q}}{q^k}.$$

Using (17) and (18) in (15), and taking into account that

$$1 - (q-1)\sum_{k\ge1} \frac{1}{(q-1)q^{2k-1}} = \frac{q^2-q-1}{q^2-1} = \alpha_q,$$

we get (14) and thus finish the proof. □

Theorem 7. *For any prime q,*

$$\sum_{n\le x} |\varphi(n)|_q = \big(\gamma_q + o(1)\big)\, x(\log x)^{-q/(q^2-1)},$$

where γ_q is a constant depending only on q.

Proof. For $p \ne q$, we have

$$\sum_{\nu=0}^{\infty} \frac{|\varphi(p^\nu)|_q}{p^\nu} = 1 + \sum_{\nu=1}^{\infty} \frac{|p-1|_q}{p^\nu} = \frac{|p-1|_q}{p-1},$$

and certainly

$$\sum_{\nu=0}^{\infty} \frac{|\varphi(q^\nu)|_q}{q^\nu} = 1 + \sum_{\nu=1}^{\infty} \frac{1}{q^{2\nu-1}} = 1 + \frac{q}{q^2-1} = \frac{q^2+q-1}{q^2-1}.$$

Combining Lemma 3 and Lemma 4, we obtain the desired result. □

We now show that the classical *Turán–Kubilius* inequality can be used to study the normal order of $\nu_q(\varphi(n))$.

Theorem 8. *For any prime q, the estimate*

$$\nu_q(\varphi(n)) = \left(\frac{q}{(q-1)^2} + o(1)\right)\log_2 n$$

holds for almost all positive integers n.

Proof. Because $\nu_q(\varphi(n))$ is an additive function, by the Turán–Kubilius inequality (see [14], [19]), we have

$$\frac{1}{x}\sum_{n\le x}\left|\nu_q(\varphi(n)) - A_q(x)\right|^2 \ll D_q(x)$$

where

$$A_q(x) = \sum_{p^r\le x}\frac{\nu_q(\varphi(p^r))}{p^r} \quad \text{and} \quad D_q(x) = \sum_{p^r\le x}\frac{\nu_q^2(\varphi(p^r))}{p^r},$$

and in both sums the summation is extended over all prime powers $p^r \le x$. Thus, it is enough to show that

$$A_q(x) = \left(\frac{q}{(q-1)^2} + o(1)\right)\log_2 x \quad \text{and} \quad D(x) = o((\log_2 x)^2). \tag{19}$$

Because $\nu_q(\varphi(p)) \ll \log p$, using the Prime Number Theorem, we derive that

$$\sum_{\substack{p^r\le x\\ r\ge 2}}\frac{\nu_q(\varphi(p))}{p^r} \ll \sum_{r=2}^{x}\sum_{k=2}^{\infty}\frac{\log k}{(0.5k\log k)^r} \ll \sum_{r=2}^{x}\sum_{k=2}^{\infty}\frac{1}{k^r} \ll \sum_{r=2}^{x}2^{-r} \ll 1.$$

Thus

$$A_q(x) = \sum_{p\le x}\frac{\nu_q(\varphi(p))}{p} + O(1) = \sum_{\substack{p\le x\\ p\ne q}}\frac{\nu_q(\varphi(p))}{p} + O(1).$$

Furthermore, as in the proof of Lemma 4, we derive that

$$\begin{aligned}\sum_{\substack{p\le x\\ p\ne q}}\frac{\nu_q(\varphi(p))}{p} &= \sum_{k=1}^{\infty}\Bigg(\sum_{\substack{p\le x\\ p\equiv 1 \pmod{q^k}}}\frac{k}{p} - \sum_{\substack{p\le x\\ p\equiv 1 \pmod{q^{k+1}}}}\frac{k}{p}\Bigg)\\ &= \sum_{k=1}^{\infty}S(x,q^k) = \left(\frac{q}{(q-1)^2} + o(1)\right)\log_2 x.\end{aligned}$$

Similar arguments show that $D_q(x) = O(\log_2 x)$ (in fact, our arguments give an asymptotic formula for $D_q(x)$). Therefore, we obtain (19), which finishes the proof. □

4. Distribution of $\Omega(\varphi(n)) - \omega(\varphi(n))$

It has been shown in [8] that for almost all positive integers n, both $\Omega(\varphi(n))$ and $\omega(\varphi(n))$ are close to $0.5(\log_2 n)^2$. Here, we study the behavior of the difference $\Omega(\varphi(n)) - \omega(\varphi(n))$.

Theorem 9. *The estimate*

$$\Omega(\varphi(n)) - \omega(\varphi(n)) = (1 + o(1)) \log_2 n \log_4 n$$

holds for almost all positive integers n.

Proof. By Theorem 5, we know that

$$\Omega(\xi(n)) = (1 + o(1)) \log_2 n \log_4 n$$

holds for almost all positive integers n. Since

$$\Omega(\varphi(n)) - \omega(\varphi(n)) = \Omega(\varphi(n)) - \omega(\lambda(n)) \geq \Omega(\varphi(n)) - \Omega(\lambda(n)) \geq \Omega(\xi(n)),$$

we see that

$$\Omega(\varphi(n)) - \omega(\varphi(n)) \geq (1 + o(1)) \log_2 n \log_4 n$$

holds for almost all positive integers n.

To obtain the upper bound, let x be a large positive real number, and let $y = (\log_2 x)^2$. The argument on page 404 of [16] shows that the set of all positive integers $n \leq x$ such that $\varphi(n)$ is not divisible by the square of any prime $q > y$ has cardinality $x + o(x)$ (see the bound on $\#\mathcal{E}_2$ in Theorem 9 of [16]). Thus, for all but $o(x)$ positive integers $n \leq x$, we have that

$$\Omega(\varphi(n)) - \omega(\varphi(n)) = \Omega_y(\varphi(n)) - \omega_y(\varphi(n)) \leq \Omega_y(\varphi(n)).$$

Now using (9) (which is established with the same value of y), we finish the proof. □
