Gallo-Roman Terra Sigillata Imitations: an attempt of attribution of some potters to their production centres

Abstract

This work deals with the archaeometric analysis of imperial age Gallo-Roman Terra Sigillata imitations (TSI) from Switzerland. The main aim of this study was to define the mineralogical and chemical characteristics of these ceramics in order to obtain information concerning raw materials and techniques used in the past.

In particular, this paper is part of a PhD thesis on TSI stamped ceramics coming from different sites in Switzerland. The dissertation investigated the origin of stamped sherds based on the establishment of three new reference groups consisting of local and homogeneous tableware produced at Lausanne Stade, Yverdon Faustus and Avenches N-E ateliers. These three homogeneous groups were used as reference to compare chemical composition of 47 fragments of stamped TSI found in Martigny, Lausanne, Avenches, Nyon, Vindonissa and Yverdon. The aim was to identify their production places as well as the working sites of the potter who signed them on the bottom.

The study did disclose that FAUSTUS worked in a homonymous workshop. It can also be affirmed that no potter worked in Avenches N-E. The results allow to suppose that QUINTUS, SABINUS and ILLANUA worked at Lausanne Stade, although this is not expressed by a perfect chemical correspondence.

Résumé

Ce travail porte sur l'étude archéométrique d'imitations de terre sigillée du 1er s. apr. J.-C. trouvées en Suisse. Le but de cette recherche était la définition des caractéristiques minéralogiques et chimiques de la céramique afin d'obtenir des informations sur les matières premières et la technique de production utilisées par les artisans gallo-romains.

En particulier, cette publication n'est qu'un extrait d'une thèse de doctorat qui s'était occupée d'abord de la définition de trois nouveaux groupes de référence de céramiques produites dans les ateliers de Lausanne Stade, Yverdon Faustus et Avenches N-E et deuxièmement de l'origine de productions estampillées. On ne discutera ici que les principaux résultats de cette deuxième partie.

Pour ce faire, les trois groupes ont été utilisés comme références pour comparer des tessons estampillés du même type de céramique et trouvés à Martigny, Lausanne, Avenches, Nyon, Vindonissa, Yverdon. Le but était de connaître les lieux de production ainsi que les ateliers des potiers qui signèrent ces céramiques. Cette étude montre qu'on peut associer la production de FAUSTUS à un atelier homonyme à Yverdon et qu'aucun des autres potiers n'a travaillé dans les ateliers du secteur NE d'Avenches. En ce qui concerne l'atelier du Stade à Lausanne, les résultats suggèrent que QUINTUS, SABINUS, ILLANUA, ont travaillé là, même si la correspondance chimique n'est pas parfaite.

1. Introduction: Terra sigillata imitations and analytical approach

Emblematic of the ceramic facies of the early Roman period on the Swiss Plateau, the «helvetic» sigillata imitations (TSI) consist of a group of orange or black tableware (Luginbühl/Schneiter 1994; Luginbühl 1995a, b) that was produced between the mid-Augustean and mid-Antonine periods (from about 15 BC–150 A.D). These wares imitate the techniques of imported sigillata, but a large part of the forms and shapes are of native tradition. Occasionally the ceramics present stamps of major interest for the study of the organisation of the production and history of the manufacturers. Well known since W. Drack's monograph (Drack 1945), this set of productions has recently been the subject of a doctoral thesis at the University of Lausanne (Luginbühl 2000). This work was accomplished simultaneously with a doctoral thesis at the University of Fribourg (Zanco 1999) dedicated to a large program of physical and chemical analyses. This paper presents the principal results of the PhD thesis of A. Zanco. Zanco's work focused on the study of production techniques (clay selection, slip preparation, firing temperature, etc....) and chemical composition of TSI from three major workshops in Switzerland: Lousonna Stade, Yverdon Faustus, and Avenches N-E. Her analysis results have permitted to determine three new reference groups from sets of wasters found in these three workshops. The mineralogical and chemical particularities of these reference groups specific to TSI which added to the ones earlier defined for the Lausanne workshop of *La Péniche* (Maggetti 1980), were subsequently compared to the stamped pieces to attempt to attribute them to production centres. The 92 analysed fragments bearing the names of 35 different potters allows only a few true demonstrations because of the rareness of workshop's reference groups. It gave nevertheless relevant information, that acquires its full significance when compared to workshops wasters and by the distribution of the different stamp types.

more than one particular production centre. Moreover, each potter seemed to have slightly differing «composition» recipes for his production, although the petrographic-mineralogical features are similar for sherds of different potters.

After a short description of the petrographic characteristics, the investigation will concentrate on the chemical approach: these results, here presented as bivariant diagrams of major and trace elements, were not exhaustive to ascertain provenance; for a successful interpretation, cluster and discriminant elaborations were necessary. In particular, Mahalanobis (M) distance histograms or their values were very helpful for comprehension.

Regarding the bivariant diagrams and the results of the discriminant analysis, only the most important and exhaustive will be discussed in the following pages.

For all the other potters' analyses and diagrams, refer to Zanco (1999) and Luginbühl (2000).

2. Research aims

This work describes a part of the analyses carried out on stamped sherds (figure 1) of various potters from the most important Gallo-Roman sites in Western Switzerland. From 92 samples excavated in different places and provided by local museums, only the most represented and important potters are discussed here. In fact, while some important and well-known potters (such as VILLO, VEPOTALUS, FAUSTUS and SABINUS) could be represented and studied by several analyses (from 7 to 12 samples), others (COIUS, GENIALIS, PINDARUS, QUINTUS, ASPRENAS, ILLANUA, IUCUNDUS, PINDARUS, IUVENIS) were only studied on a few sherds (between 2 and 7). Lastly, 22 stamps (CICUS, AEI CRITI, ALBINUS, C. SAT., SOILLUS, GENTILIS, SEXTIUS, MELUS, FRONTO, CINCE«SS», CIUS, IUSTUS, METILLIUS, MURRANUS, RESPECTUS, TERTIUS, CATU(SIUS), DIOMEDES, FELIX, LICCATUS, DABINATUS, FLORUS) provided only one ceramic sample. We discuss here the ceramics signed by VILLO, VEPOTALUS, FAUSTUS, SABINUS, QUINTUS and ILLANUA.

The aims of this study were to define the geographical provenance of products found at the different sites, attribute them to the workshops and evaluate the possible existence of workshop branches.

To define the geographical provenance of products found of different places, chemical data were compared with data from previously defined reference groups (see paragraph 4). Firstly the sherds were examined on their mineralogical and petrographic aspects. All the samples showed similar petrographic chareacteristics under the microscope. X-ray analysis revealed phases that indicate

3. Sampling and analytical methods

Forty seven samples (tab. 1) excavated at different places were provided by local museums as follows:

20 samples from Lausanne («Musée Romain de Lousonna-Vidy»); 3 from Yverdon («Musée du Château d'Yverdon»); 1 from Atelier du Faustus, (Yverdon); 7 from Avenches («Musée Romain d'Avenches»); 10 from Vindonissa («Vindonissa-Museum») and 6 from Martigny («Office de recherches archéologiques de Martigny»).

The applied methods were the following:

- Quantitative chemical analysis by X-ray fluorescence (PHILIPS PW 2400 spectrometer, Institute of Mineralogy and Petrography, University of Fribourg) of major and minor elements (Si, Ti, Al, Fe, Mn, Mg, Ca, Na, K, P) and trace elements (Ba, Cr, Cu, Nb, Ni, Pb, Rb, Sr, Y, V, Zn, Zr). Samples were prepared as described in Zanco (1999). Chemical data are available in table 2.
- Phase analysis by powder X-ray diffraction (PHILIPS PW 1800 diffractometer, Institute of Mineralogy and Petrography, University of Fribourg), to investigate the mineralogical composition and evaluate the maximum firing temperature (Peters/Iberg 1978; Maggetti 1981).
- Polarisation microscopy for fabric analysis (matrix and temper characterisation).
- Statistical applications: uni- and bivariant analyses, cluster analysis with average and single linkage methods based on Euclidean distances calculated on 16 elements (SiO_2, TiO_2, $Al2O_3$, Fe_{tot} (as Fe_2O_3), MgO,

CaO, Na_2O, K_2O, Cr, Ni, Rb, Sr, V, Zn, and Zr), M distances calculated on the same elements and discriminant analysis based on Mahalanobis distances (Wilkinson 1989).

We assumed that an attribution could be stated if the M distance of a sherd of unknown origin shows values comprised between the minimum and maximum M distance values of the comparing reference group (Picon 1984).

FeO was determined only for the samples for which sufficient material was available. For FeO analysis the Di-pyridil method was employed (Koester 1979).

4. The Reference groups

The following section presents a short description of TSI reference group characteristics. Chemical data are available at the web site: http//www.unifr.ch/mineral.

- CH 39 represents the Lausanne Stade reference group, which was active during the 1st century A.D. This group comprises of 36 homogeneous calcium-rich samples with a mixed, fine matrix. Calcite is well developed in the porosities. Maximum firing temperatures are estimated at around 950°C. Besides this homogeneous group, 10 other sherds were characterised and, as they were not definitely imported, re-used in the attribution study. The local origin of this large number of TS imitations was attested by the presence of kiln fragments and loom weights.
- CH 40, or the Yverdon *Faustus* (30/60 A.C) workshop, a very homogeneous reference group with a chemical character not far from that of Lausanne Stade, consists of 28 samples, normally fired in an oxidising atmosphere and characterised by a fine matrix. Also in these textures, the porosities are filled by calcite, in mono- or poly-crystals. Firing temperature was in the range 850°–950°C, sometimes attaining >950°C.
- CH 41, Avenches N-E workshop. This centre was in activity during the second half of the 1st century A.D. It is represented by 25 samples, with a fine, temper-poor matrix. Many clay pellets and iron oxide spots are distributed in the groundmass. Most of the samples were fired in reducing conditions.

5. Attribution examples: major and minor potters

As CH 14 (La Péniche), CH 18 (Baden B; Jornet 1982) CH 19 (Baden + Augst), CH 22 (Bern; Jornet 1982) and CH 24 (Lausanne 2) were ceramic productions considered to be similar to TS imitations, attributions

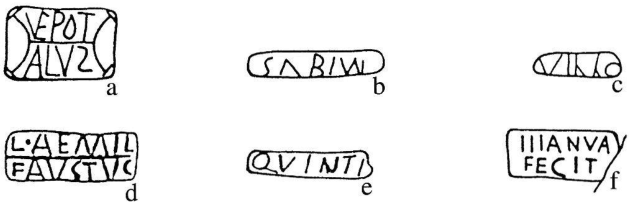

Fig. 1. Examples of the six studied potters' stamps. a VEPOTALUS; b SABINUS; c VILLO; d FAUSTUS; e QUINTUS; f ILLANUA.

were made on these groups. They were carried out in two stages, comparing first stamped production with CH 18, 22, 24 and then with CH 14 and 19.

CH 14 and 24 were established by Kaenel et al. (1982) in their study on several Gallo-Roman workshops found in the neighbourhood of Lausanne, presenting different ceramic categories and types. These production centres were not far from that of Lausanne Stade (especially La Péniche), and so it is not surprising to find more similarities with the production centres near Lausanne than with those of Bern, Baden B and Baden + Augst. The latter were too far away, and more difficult to reach or the potters. Also the results of discriminant analysis made on CH 18, 19 and 22 confirmed that no real possibility of attribution existed for these references. Moreover, none of the sample seems to belong to La Péniche workshop.

Only one reference group, CH 24 (Lausanne 2), consisting of CaO-rich TS from different sectors («Sector 25», «Sector 23», «Forum» and «Marchand»), shows correspondence with the stamped samples. Some similarity was found with ZA 114 from Lausanne, on which the signature *QUINTUS* can be read. It is worth noting that these similar appearances are always expressed by marginal M distance values. Table 3 shows the results of discriminant analysis.

The correlations of CH 39 (Lausanne Stade), CH 40 (Yverdon *Faustus*) and CH 41 (Avenches N-E) were first carried out considering each workshop and all the stamps by means of cluster analysis. Dendrograms (Zanco 1999) already provided an approximate description of what was later found with discriminant analysis. A sharp separation indicates that samples from Yverdon *Faustus* and Avenches N-E are each very homogeneous; no similarity put stamped sherds in relation with the Avenches N-E reference, while for the Yverdon *Faustus* group, only one sample, ZA 80, appears in its cluster. The situation is slightly different in Lausanne Stade, where the general pattern of the group is mixed with some stamped samples, indicating similar chemical characteristics.

5.1. Major potters

5.1.1. VEPOTALUS

Eleven samples, stamped with the name VEPOTALUS, were analysed: three were found in Lausanne (ZA 126, 150, 154), three in Avenches (ZA 185, 186, 187), two in Martigny (ZA 207, 208), one in Vindonissa (ZA 205), one in Yverdon (ZA 161) and one in Nyon (ZA 216). They are all cup or plate fragments, except ZA 216, which is indefinite.

All ceramic pastes stamped VEPOTALUS contain large amounts of quartz, plagioclase, K-feldspar and pyroxene. Illite is frequent. Calcite was detected in some samples. Phase analysis sometimes reveals hematite and gehlenite as well as spinel.

Under the microscope, the matrix appears fine-grained and temper-poor; it is mixed, siliceous-carbonatic. Small quartz and plagioclase crystals are observed, as well as small metamorphic rock fragments. Secondary calcite often occupies the porosity. Brownish-red grains, of various sizes and in different proportions, spot the ceramic paste.

The VEPOTALUS samples may be considered as being chemically heterogeneous. This characteristic indicates different provenances for the samples and therefore the existence of several production centres.

From the archaeological point of view (Luginühl 2001), the location of VEPOTALUS' *officina* at Avenches is very interesting, also because this potter, whose production began around 15–10 A.D., was the pioneer of TS imitations on the Helvetic territory. In spi-

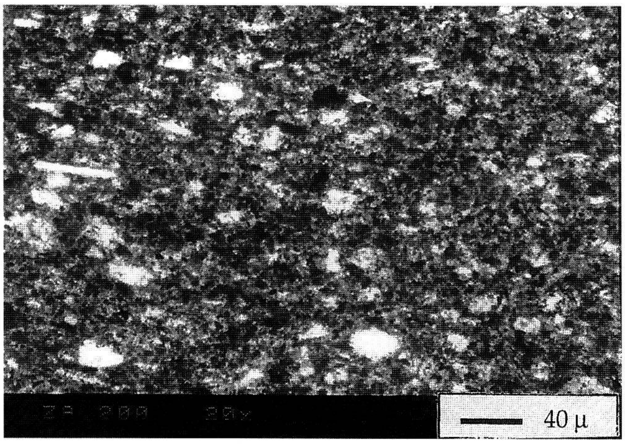

Fig. 3. ZA 200: microscopic aspect of a sherd carryng the name of SABINUS. Inside the fine and temper-poor matrix some quartz, plagioclase, chert and muscovite grains were detected. Calcite is often in the porosity. (Magnification 20×; PPL).

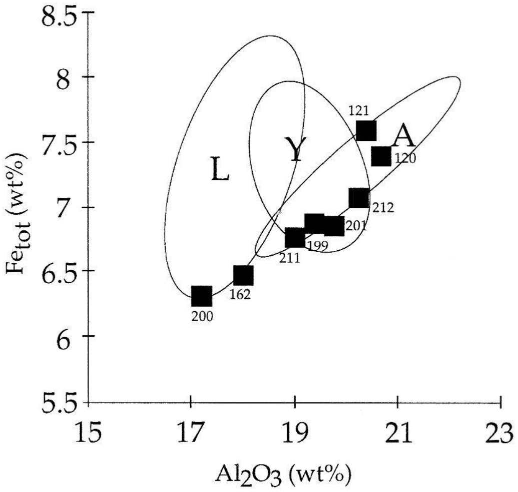

Fig. 5. Fe_{tot}/Al_2O_3 comparing Lausanne Stade, Yverdon Faustus and Avenches N-E with SABINUS samples. L Lausanne Stade; Y Yverdon Faustus; A Avenches N-E.

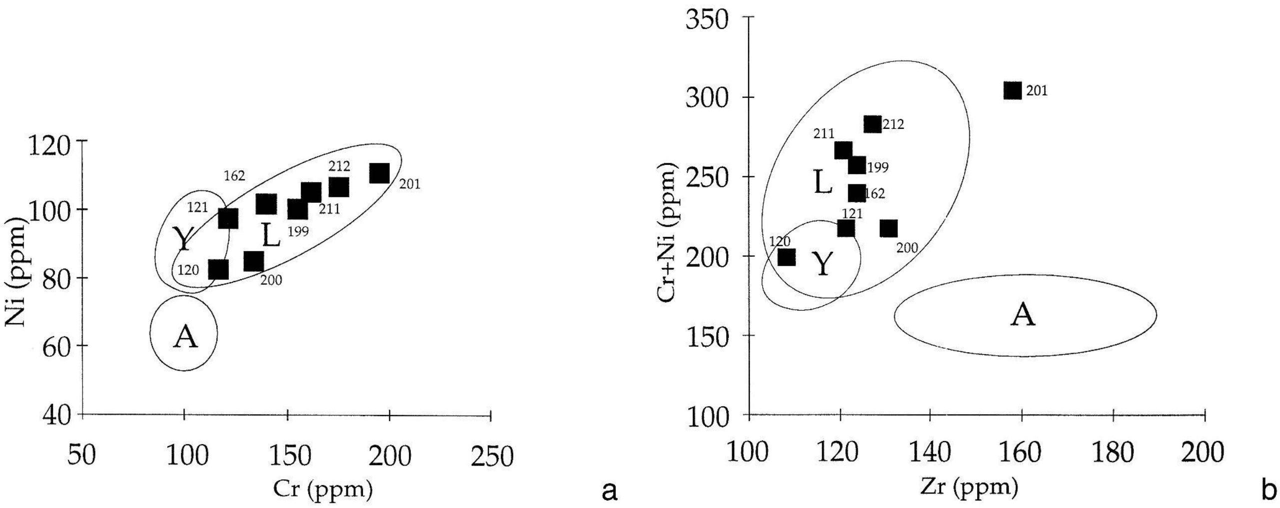

Fig. 4. SABINUS stamps and the three reference groups in the bivariant diagrams Ni/Cr (a) and Cr+Ni/Zr (b). SABINUS = ■. L Lausanne Stade; Y Yverdon Faustus; A Avenches N-E.

te of the great number of stamps of this potter in the *Caput Civitatis*, our results do not confirm that VEPOTALUS' workshop was located in the Avenches region. Considering the bivariant diagrams (CaO/MgO and Cr+Ni/Zr) of Figure 2 and the M distance distribution (tab. 4), this potter does not show any correspondance with the reference groups considered here. No attribution can be made, as far as the previously defined reference groups are concerned. Table 4 summarises M distances for VEPOTALUS samples and the three workshops. No sherd shows a value included within the patterns of the groups or marginal to them.

5.1.2. SABINUS

Eight SABINUS samples were analysed. Also in this case, they came from various places: Lousonna ZA 120, 121, Vindonissa (ZA 199, 200, 201), Martigny (ZA 211, 212) and Yverdon (ZA 162).

Contrary to the opinion of Drack (1945), who placed SABINUS' workshop at Vindonissa, Stähli (1975) supposed the centre of production to be in Lausanne Stade. His arguments are supported by the fact that this potter was the most important during the reigns of Tiberius and Claudius, when this workshop was at its peak.

The mineralogical composition of SABINUS products reveals the presence of quartz, plagioclase, K-feldspars, pyroxene and also illite in all samples. Their calcium-rich character is testified by the frequent detection

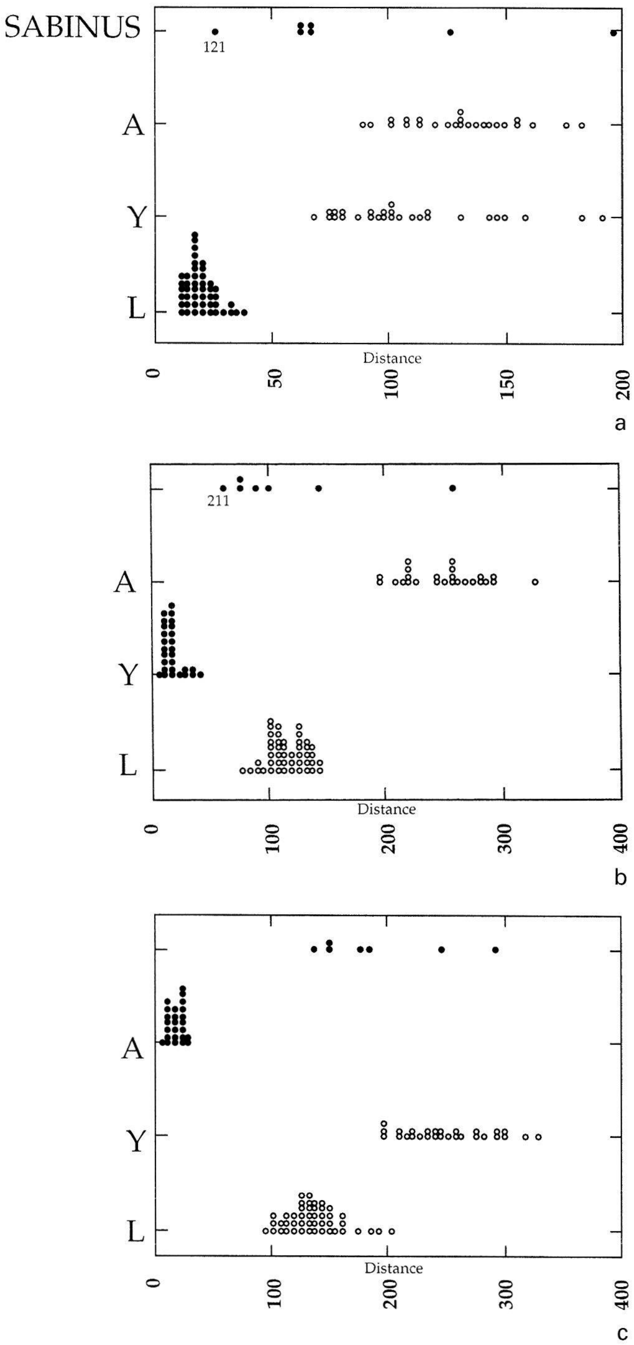

Fig. 6. M distances of SABINUS stamped sherds calculated in relation to the three reference groups of a) Lausanne Stade (= L), b) Yverdon Faustus (= Y), c) Avenches N-E (= A) concerning SiO_2, TiO_2, Al_2O_3, MgO, CaO, Na_2O, K_2O and Fe_{tot} as major elements, and Cr, Nb, Ni, Rb, Sr, Th, V, Y, Zn and Zr as trace elements.

of gehlenite and pyroxene (diopside). For most of the samples, the maximum firing temperature ranged between 850° and 950°C.

All the samples show a very fine carbonatic and temper-poor matrix. Small and rare quartz, plagioclase, chert and muscovite grains are visible. Calcite is often inside the pores. Sometimes clay pellets (especially in ZA 120, 121, 162, 200; fig. 3) are observed. The maximum diameter of the inclusions measures 0.5 mm, belonging to an argillaceous rock fragment in sample ZA 121. Although all samples show very similar petrographic characteristics, a further distinction is possible: ZA 120 with ZA 121 is identical and little temper-poorer than the others and ZA 211 and 212 (both found in Martigny). Another small group is represented by ZA 199, 200 and 201 found at Vindonissa. The temper-richest example is sample ZA 162.

The production centre in Lausanne Stade appears to be the closest to these stamped sherds as major and trace element diagrams Ni/Cr, Cr+Ni/Zr and Fe_{tot}/Al_2O_3, show (figs. 4.5), also because 21 occurrences were found in it. However, the eight SABINUS TS imitations are not chemically homogeneous. In particular, SABINUS sherds from Yverdon and Vindonissa (ZA 162, 199, 200, 201), whose chronology, quality and style allow to believe they have been produced by the same potter, show different behaviour from samples from Lausanne (ZA 120, 121) and Martigny (ZA 211, 212), especially considering their MgO and K_2O contents. In spite of these arguments, results of discriminant analysis (fig. 6) attest good similarity between sample ZA 121 and the Lausanne reference group, while ZA 211 is very marginally correlated to FAUSTUS' site in Yverdon.

5.1.3. VILLO

VILLO is the best represented potter, as 12 samples were available for analysis. ZA 188 and 189 are cup fragments and were found at Avenches; the others are all plate fragments. ZA 196, 197 and 198 come from Vindonissa; ZA 209 and 210 from Martigny. The others come from Lausanne.

Almost all the sherds stamped by VILLO were fired at a maximum temperature of 850°–950°C, as attested by the mineralogical phases of quartz, plagioclase, K-feldspars, illite and pyroxene. Calcite (considered as secondary mineral) is also often detected. Gehlenite confirms a maximum firing temperature of 950°C. Wairakite and hematite are sometimes found.

The ceramic pastes of VILLO may be divided into two groups on the basis of their petrographic characteristics. The first group contains ZA 158, 132, 197, 196, 209,

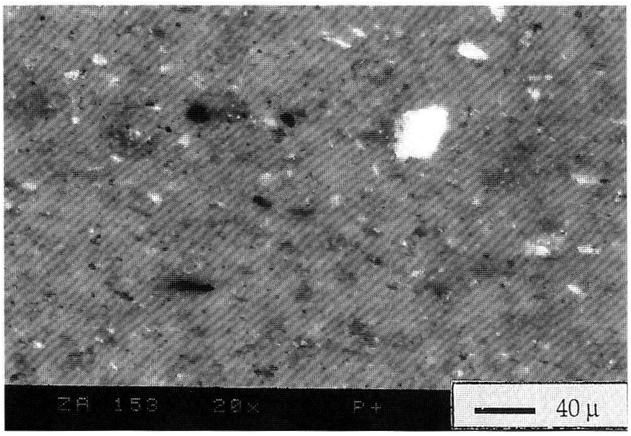

Fig. 7. ZA 153: this sample signed by VILLO is characterised by a mixed matrix very fine and temper-poor. Many iron oxyde grains spot the groundmass. (Magnification 20×; XPL).

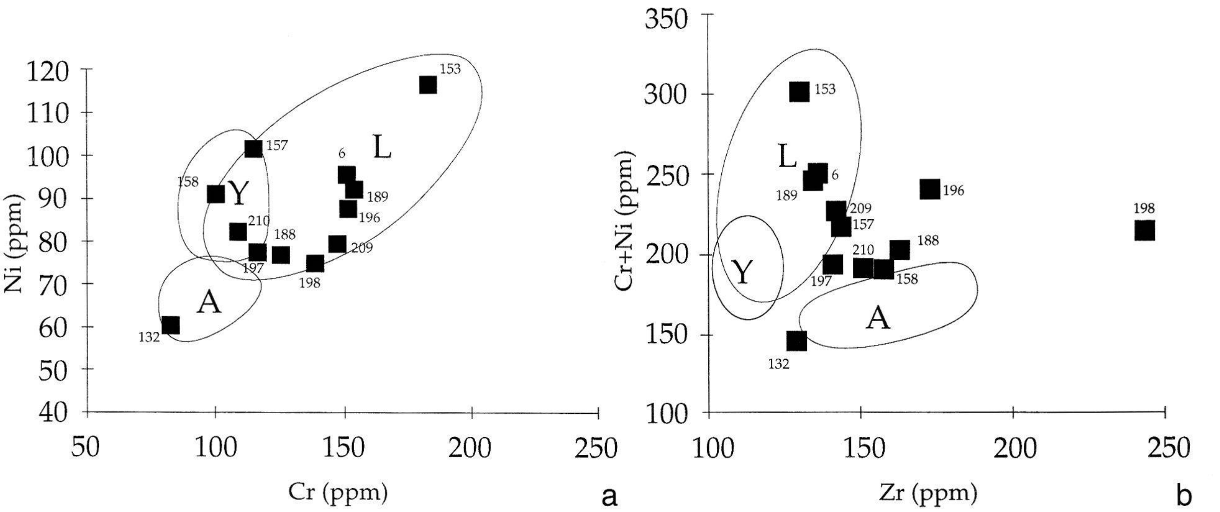

Fig. 8. Sample distribution for VILLO and the three new reference groups with bivariant diagrams Ni/Cr (a) and Cr+Ni/Zr (b). VILLO = ■. L Lausanne Stade; Y Yverdon Faustus; A Avenches N-E.

188 and 198: it shows a fine, porous matrix with a few quartz crystals homogeneously distributed in the groundmass. The second group (fig. 7) has a finer grained and mixed matrix. Both contain many red iron oxide spots.

VILLO specimens exhibit a heterogeneous chemical tendency, especially in Al_2O_3, MgO, CaO and Sr distribution. Sample ZA 153 is characterised by a behaviour similar to that of the Lausanne group, differentiating from its general pattern for the greater CaO content. In the diagrams MgO/Al_2O_3, CaO/MgO and Fe_{tot}/Al_2O_3, ZA 189 and 157 appear to be similar respectively to the Yverdon *Faustus* and Avenches N-E groups, but, according to immobile element diagrams (fig. 8) Ni/Cr and Cr+Ni/Zr, these products seem to originate from Lausanne Stade. Discriminant analysis (fig. 9) through M distance histograms confirm their marginal position to this production centre. Thus, no attribution can be ascertained: it can only be concluded that there is a greater similarity to Lausanne Stade (ZA 153) and Yverdon (ZA 189) than to Avenches.

5.1.4. FAUSTUS

Cup fragments ZA 8, 4, 12 were found at Lausanne; ZA 133 is an unidentified type of ceramic, and ZA 202 and 203 are fragments of plates coming from the Roman Museum in Avenches. ZA 80 is the stamped waste sample already described in the reference group definition.

Of the seven samples signed by FAUSTUS, six are composed of quartz, plagioclase, pyroxene, K-feldspar and illite. Calcite was also detected in all the samples. Only one, ZA 80 (a stamped waste), does not reveal the presence of illite, but it contains gehlenite, indicating a maximum firing temperature of about 950°C.

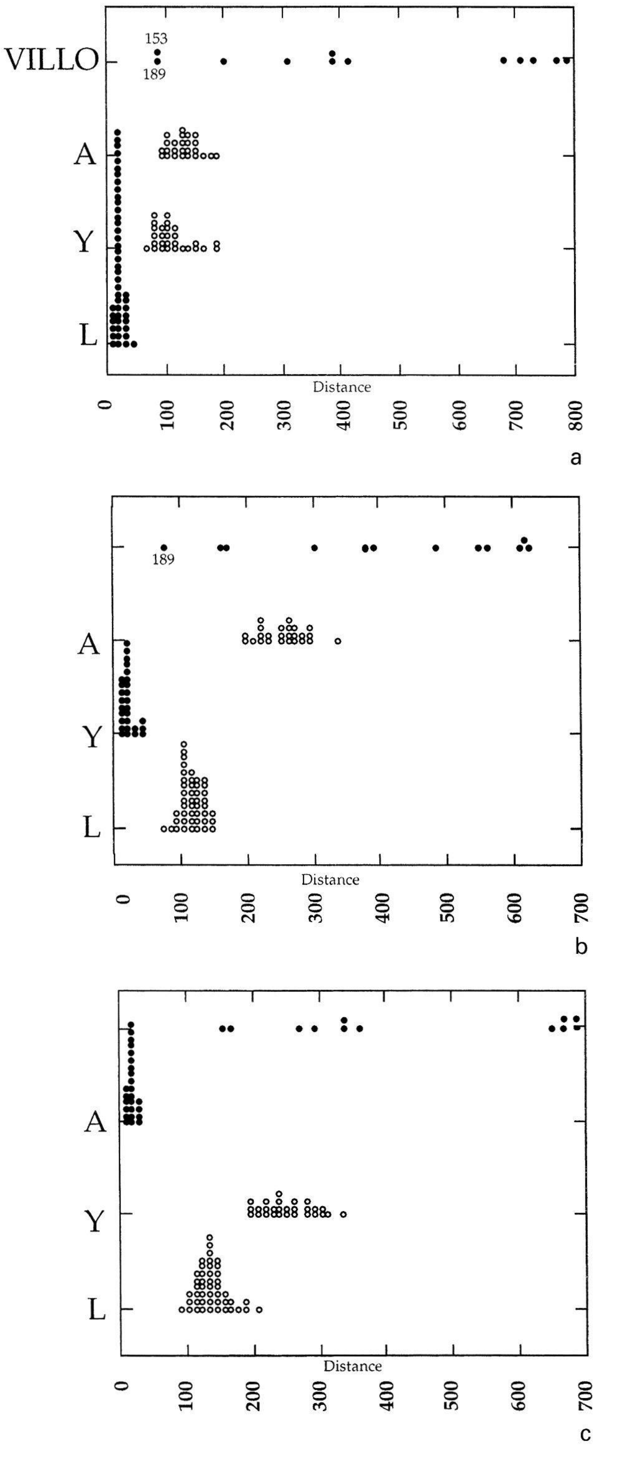

Fig. 9. M distances of VILLO stamped sherds calculated in relation to the three reference groups of a) Lausanne Stade (= L), b) Yverdon Faustus (= Y), c) Avenches N-E (= A) concerning SiO_2, TiO_2, $Al2O_3$, MgO, CaO, Na_2O, K_2O and Fe_{tot} as major elements, and Cr, Nb, Ni, Rb, Sr, Th, V, Y, Zn and Zr as trace elements.

Petrographic analysis revealed the fine carbonatic and temper-poor matrix characterising the production of FAUSTUS. Tempers are made up of small monocrystalline and polycrystalline quartz and feldspars. Rare muscovite and chert are also observed, as well as clay pellets. Calcite fills the pores. Maximum diameter is about 0.8 mm.

Sample ZA 80 is the only one really well linked to the reference group of Yverdon *Faustus:* as a matter of fact, from the archaeological point of view, it is a stamped waster, and the presence of FAUSTUS in the Yverdon production centre is undoubted.

In spite of this evidence, other sherds carrying the same signature seem to indicate a different attribution. They show different chemical characteristics compared with the Yverdon reference group and to ZA 80 (figs 10.11), as they contain more SiO_2, TiO_2 and Zn and less MnO, CaO and MgO. ZA 133 and 112 occupy a rather marginal position with reference to Lausanne Stade, as the M distance histograms show in figure 12.

5.2. Minor potters

5.2.1. QUINTUS

Seven samples with the name QUINTUS were submitted to analysis. ZA 114, 115, 116, 149 and 156 are from Lausanne, ZA 180 was found at Avenches, and ZA 204 at Vindonissa. All are plate or cup fragments.

From the mineralogical point of view, samples carrying QUINTUS' name are composed of quartz, plagioclase, K-feldspar and illite (except ZA 156) and a peak at 3.03 ° always reveals the presence of calcite. Hematite was also detected in all the samples.

This fact suggests a firing temperature between 850°–950°C for the majority of samples, and >950°C in the case of ZA 156. It was not possible to perform XRD analysis on sample ZA 180.

Three samples (ZA 114, 115, 116) show identical microscopic structures represented by a fine, siliceous temper-poor matrix. Quartz monocrystals and polycrystals, as well as plagioclase and muscovite, are observed. ZA 204 is characterised by a more temper-poor and finer matrix, and ZA 156 contains large amounts of secondary calcite in the porosities.

All the sherds were fired in oxidising conditions. This is evident from the presence of many red iron clots, distributed in the texture.

These samples, certainly produced by the same artisan (close stylistic similarity between the two known stamp's types), are heterogeneous and differ in their chemical behaviour when compared with the groups, but the M distance value list (tab. 5) calculated in comparison with

Tab. 5. M distances calculated for QUINTUS samples in relation to Lausanne Stade, Yverdon Faustus and Avenches N-E. Maximum and minimum values for the three groups are also included. Distances obtained using SiO_2, TiO_2, Al_2O_3, MgO, CaO, Na_2O, K_2O, Fe_{tot}, Cr, Rb, Sr, Zn and Zr.

Lausanne Stade, Yverdon Faustus and Avenches N-E shows a high probability that *QUINTUS* was present in the first workshop. The bivariant diagrams of Figure 13 attest the chemical heterogeneity of these samples and their distribution corresponding to the reference groups. These results are confirmed by discriminant analysis: according to the M distances, ZA 114, 156 and 204 reflect, in decreasing order, the probability of originating from the Lausanne Stade workshop.

5.2.2. ILLANUA

The two sherds with the stamped name of ILLANUA, ZA 10 and 173, excavated respectively in Lausanne and Avenches, are fragments of a plate and a cup, both fired in a reducing atmosphere.

Under the microscope they are very similar showing a fine-grained, temper-poor matrix with only a few quartz crystals distributed in the groundmass. Secondary calcite covers the rims of the pores. A few, very small muscovite and feldspar crystals are also observed.

Looking at the position of ILLANUA stamps in the bivariant diagrams (fig. 14) and the results of discriminant analysis (tab. 6) it is clear that:

- ZA 10 is very close to the Lausanne Stade group;
- ZA 173 does not show constant behaviour compared with the groups;
- both samples, attesting ILLANUA's production, are not identical: they differ in their MgO, K_2O, Cr, Fe_{tot} and Al_2O_3 contents.

It may be concluded that only one of the ILLANUA sherds was made with a clay that was very similar to the raw material used in the Lausanne Stade worshop.

Tab. 6. M distances calculated for ILLANUA samples in relation to Lausanne Stade, Yverdon Faustus and Avenches N-E. Maximum and minimum values for the three groups are also included. Distances obtained using SiO_2, TiO_2, Al_2O_3, MgO, CaO, Na_2O, K_2O, Fe_{tot}, Cr, Rb, Sr, Zn and Zr.

6. Discussion

Attribution of a sherd to a specific group is no simple task. The decision to link a sample to a reference group of a specific area depends on affinity of composition, validity rules (mineralogical, petrographical and technical) and *a priori* probability (geological, geographical, historical and archaeological framework; Picon 1984). Attribution of a group of sherds of uncertain origin is generally easier, since more information is available on the distribution and average values of single elements. This was not the case for the sherds examined in this study as they formed groups which were too small to have statistical relevance. Moreover, the production of each potter is very heterogeneous, as may clearly be seen when comparing the M distance histograms.

If a sample shows no similarity with the reference groups used for the comparison, there may be different reasons for this fact. The choice of samples must be taken into consideration, since the material is sometimes not sufficient to be representative of a specific potter. The availability of reference groups is a further problem: for instance, if no sample seems to originate from the Avenches N-E group, this does not mean that unknown reference groups in Avenches could better meet similarity requirements for these samples. It may be concluded that samples of unknown provenance do not belong to Avenches N-E, but in the future some other Avenches reference groups may explain the origin of our stamped sherds.

Another problem is the contamination during burial, which may affect and change the original composition of the reference sherds and distort information on raw materials used in the past. This problem can be minimized

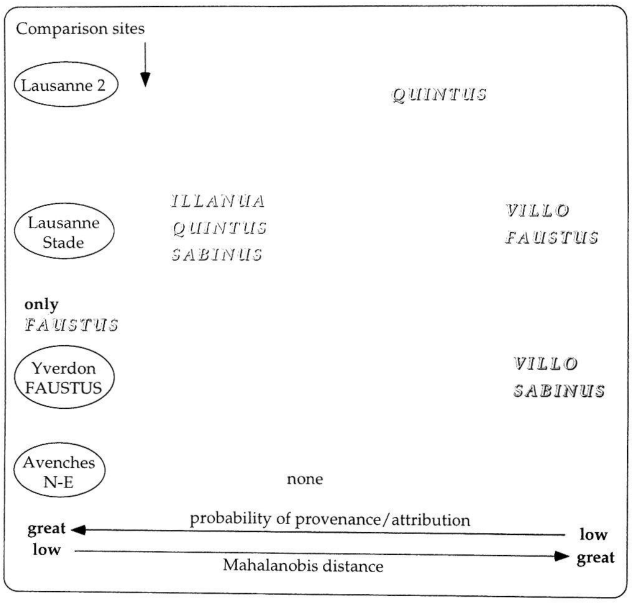

Fig. 15. Summary of results of attribution study and potters' hypothetical places of work.

using a mathematical correction on the major element totals (see Zanco 1999).

The production centre may have been located in different sub-workshops, in which ceramics were signed with the name of the leading founder, or the same potter may have worked in different places using different clays. These are some of the reasons for the heterogeneity of sherds made by VEPOTALUS or some other potters.

In the case of the Lausanne Stade workshops, the hypothesis of a potter moving between different sub-workshops does not appear strange especially if one considers the presence of several sites in that area.

It seems unlikely that SABINUS moved from Lausanne Stade to Yverdon *Faustus*.

To sum up, and to try to answer archaeological questions, considering the limitations of statistical models and representative significance, only a very small percentage of sherds produces results that information about their origin; of 47 stamped samples, only 6 seem to indicate their probability of provenance.

With the statistical package we used (Systat) every calculation is made on the basis of predefined homogeneous reference groups. However, the group of stamped sherds is not homogeneous and therefore the evaluation with this statistical programm was impossible: for potters represented with more than 6 sherds, every sample was compared with the three established reference groups, as a consequence of the heterogeneous chemical characteristics of most of the potters' production. This was also the only way of keeping the lower and upper limits of M distances of the reference in each correlation as constant as possible. Another limitation of this program is the obligation to use at least three and at most five groups. The program does not work with only two. Every discriminant calculation is a comparison between all the samples of all the groups.

Although some M distances are closer to a reference group, all the samples show a marginal character, and no real confirmation of their provenance can be made. Therefore, only in one case, concerning the Yverdon *Faustus* reference and ZA 80, a definite attribution could be made. For all the others, we may speak of higher or lower probabilities for a sherd belonging to one reference group rather than to another. A list of probabilities can be given to the archaeologists, who will confirm and interpret this outcome, according to their own knowledge.

Figure 15 summarises the probabilities of attribution (in decreasing order) of stamped samples in the various sites.

- Concerning the Yverdon site, only one sample (ZA 80) shows a value of distances close to the lower limit of the group and can definitely be attributed to it. VILLO and SABINUS are very marginal.
- Other samples seem to have a greater probability of belonging to the group of Lausanne Stade (with the names ILLANUA, QUINTUS, SABINUS).
- No sample gives evidence of coming from Avenches.

7. Conclusions and perspectives

The workshop reference groups are still too rare to fully exploit the results concerning the stamped pieces. The information furnished by the above analyses allow us to confirm or reinforce several hypotheses concerning the attribution of craftsmen to production centres, such as the one of the Sabinus Quintus and Illanua potters to the Lausanne workshop of the *Stade*. We will not elaborate here on the «historical results» of these investigations recently presented in the *Archéologie Suisse* journal (Luginbühl 2001), but it must be recalled that these analyses bring very interesting information about the careers of the potters mentioned (Vepotalus, Villo, Faustus, Sabinus, etc. ...), as well as a large number of others, such as Pindarus, Florus, Coius or Asprenas. The archaeometric data are now completed by the data of studies concerning the distribution of the different stamp-types and by the stamps in a workshop context; together, they attest the existence of branches, movements and different types of craftsmen's associations. As far as the methodology is concerned, the analyses have demonstrated the great efficiency of the techniques employed and thus constitute a solid basis for future research on the sigillata imitations. One one hand there is no doubt that new analysis programs on groups of masters will allow to verify attribution hypotheses. On the other hand, new studies on the stamped ware, particularly comparisons between potters and no longer only between reference groups, would provide further evidence or confirmation of associations. The realisation of a small complementary program on the wares of Nyon and Augst (Zanco/Galetti 2000) has recently revealed that the Fronto potter had workshops in both agglomerations.

In archaeometry, as in other disciplines, the right questions bring the right answers.

Acknowledgments

The authors would like to thank the Museums that provided the samples: «Musée Romain de Lousonna-Vidy», «Musée du Château d'Yverdon», «Musée Romain d'Avenches, «Vindonissa-Museum» and «Office de recherches archéologiques de Martigny». Thanks are due to Prof. Marino Maggetti, of the Institute of Mineralogy and Petrography of the University of Fribourg, Switzerland, for helpful discussions.
